Foundation was particularly excepted in the act for the dissolution of colleges and chantries, in the time of Edward VI. Its establishment, however, has been in some degree altered, and now consists of a provost, seven fellows, two schoolmasters, two conductors, seven clerks, seventy scholars, and ten choristers, besides inferior officers and servants. The annual election of scholars to King's college, Cambridge, founded also by Henry VI. takes place about the end of July, or the beginning of August, when twelve of the senior boys are put on the roll to succeed in this college as vacancies occur. The average number of vacancies are about nine in two years: at nineteen years of age the scholars are superannuated. Eton college also sends two scholars to Merton college, Oxford, where they are denominated post-masters. It has a few exhibitions, of twenty-one guineas each, for its superannuated scholars, towards whose assistance Mr. Chamberlayne, a late fellow, has bequeathed an estate of *Sol. per annum*, after the death of his widow. The scholars elected to King's college succeed to fellowships at three years' standing. The independent scholars at Eton, commonly called *Oppidans*, are very numerous; the average number having been for several years past from 300 to 350: when Dr. Bernard was master, under whom the school particularly flourished, the number at one time exceeded 520. Among the many distinguished persons who received their education here we find the names of bishop Fleetwood, bishop Pearson, John Hales, Dr. Stanhope, sir Robert Walpole, Horace Walpole, Oughtred the mathematician, Boyle the philosopher, Waller, Gray, West, the late earls Camden and Chatham, and the late learned Jacob Bryant; with many other eminent literary and public characters of the present day.

An ancient custom, appertaining to this college, called the "*Montem*," or "*Ad montem*," must not be passed unnoticed. This is a procession of all the scholars, &c., made every third year on Whit-Tuesday, to a tumulus, which has acquired the name of *Salt-hill*, by which also the neighbouring inns have been long known. The chief object of this ceremony is to collect money for *salt*, as the phrase is, from all persons present, even from passengers travelling the road. The collecting scholars are called *salt-bearers*, and are dressed in rich silk habits. This ceremony has been frequently honoured with the presence of the king and royal family, whose liberal contributions, added to those of the nobility and gentry educated at Eton, who purposely attend this meeting, have so far augmented the collection, that it has been known to exceed 800*l.* The sum so collected is given to the senior scholar who is going to Cambridge for his support at the university. It would perhaps be a vain endeavour to trace the origin of all the circumstances of this singular custom, particularly that of collecting money for *salt*, which has been in use for time immemorial. The procession itself seems to have been coeval with the foundation of the college, and it has been conjectured, with much probability, that it was that of the bairn or boy bishop. It is so asserted in a note among the MS. collections bequeathed to the British Museum by Mr. Cole, who was of Eton and King's college: but whence he procured this information, which, if correct, might be decisive, does not appear. The custom of hunting a ram by the Eton scholars on Saturday in the election week, supposed to have been an ancient tenure, was abolished by the late provost Dr. Cooke.

Eton college consists of two quadrangles: in the first are the school, the chapel, and lodgings for the masters and scholars. The other is occupied by the library, the provost's lodgings, and the apartments of the fellows. The

chapel, as far as relates to its external appearance, is a very handsome structure; the inside has none of that ornamental architecture so much admired in King's college chapel at Cambridge, to which this has sometimes been compared, but is quite plain, and has been much disfigured by some injudicious alterations, made in the beginning of the last century, when several of the monuments were removed, and others concealed behind the wainscot then placed at the east end. The whole length of the chapel is 175 feet, including the ante-chapel, which is 62 feet long. Among the eminent persons who are buried in this chapel, are Richard, lord Grey of Wilton, henchman to king Henry VIII.; John Longland, bishop of Lincoln, confessor to that monarch; sir Henry Saville, the learned warden of Merton, and provost of this college, who founded the Savilian professorships of astronomy and geometry at Oxford; sir Henry Wotton, an eminent ambassador and statesman, who was also provost of Eton; Francis Rowle, a distinguished writer among the puritans, and one of the lords of Cromwell's upper-house, who died while provost of Eton in 1658; Dr. Allestree, also provost, an eminent royalist, who built the new or upper school, with the cloisters beneath, at the expence of 1500*l.*, and died in 1680; and Nathaniel Ingelo, who died in 1683. The monuments of some of the above-mentioned persons are not now to be seen. Sir Henry Wotton's tomb has the following singular inscription:

"Hic jacet hujus sententiæ primus auctor—  
Disputandi pruritus fit ecclesiarum scabies"  
"Nomen alias quære."

In the ante-chapel is a statue of the founder, by Bacon, erected in 1786; the sum of 600*l.* having been bequeathed for that purpose by the Rev. Edward Betham, fellow of the college, who died in 1783: and a monument of the young earl of Waldegrave, who was drowned when at Eton school, in 1794.

The college library contains a very large and valuable collection of books, having been from time to time enriched by munificent bequests.

In 1452 the college had a charter for a market on Wednesdays, with considerable privileges; but it has been long dissolved. Two fairs were granted by the charter of 1444: one for the three days following Ash Wednesday, the other for six days next after the 13th of August. There is now only one fair, held on Ash-Wednesday. The parish church of Eton, called in ancient records *Eton-Gildables*, having been suffered to fall to decay, the inhabitants are permitted to attend divine service in the college chapel. The provost is always rector, and has archidiaconal jurisdiction within the parish. There is a chapel of ease in the village served by one of the conductors of the college; it was built for the use of the inhabitants by William Hetherington, who had been one of the fellows, and was a very liberal benefactor to the blind and to the poor of other descriptions.

Eton is situated on the northern banks of the Thames, opposite to Windsor, with which it is connected by a bridge. It is 22 miles distant from London; consists chiefly of one street; and contains 290 houses, and 2026 inhabitants. Lysons's *Magna Britannia*, vol. i. Beauties of England and Wales, vol. i.

ETORPU, one of the Kuriskoy or Kurile islands, lying 30 versts from Urup; and about 300 versts in extent. The whole island is covered with lofty mountains; one of which, at the northern extremity, emits a continual smoke, and occasionally flames. The summits of the mountains are bald, with steep cliffs and heaps of rubbish. Here are forests, consisting of the same trees with those of the island

Urup. In the southern half, near about the centre of the island, grew larch-trees, in the proximity of the sea, but slender, though further inland, in the plains of the valleys, good timber trees, fit for the purposes of building. Here are likewise black bears, and in the forests fables and foxes are met with. Of rats there is no scarcity; fish-otters haunt the streams; and the brooks abound in fish. During the storms that happen here, whales and large dolphins are thrown ashore by the sea. The sea-otter is not seen here, but sea-lions, though not of any great dimensions. The inhabitants are hairy Kurils, who dwell together in villages. They are numbered in the capitation-tax at 92 persons.

ETREPAGNY, or ESTREPAGNI, a small town of France, in the department of the Eure, chief place of a canton in the district of Les Andélys, with a population of 1201 individuals. It is situated 9 miles from les Andélys, and 9 miles W. of Gisors; its canton contains 10,442 inhabitants, dispersed in 26 communes, on a territorial extent of 140 kilometres.

ETRIGNY, a town of France, in the department of the Saone and Loire, and district of Chalons-sur-Saone;  $3\frac{1}{2}$  leagues S. of Chalons.

ETRIS, a town of Egypt; 18 miles N.W. of Cairo.

ETROEUNG, a town of France, in the department of the North, and district of Avesnes;  $1\frac{1}{4}$  league S. of Avesnes.

ETRURIA, in *Ancient Geography*, a country of Italy, separated on the west from Liguria by the river Macra; from Latium and Umbria on the east by the Tiber; on the north-east by a part of the Apennines from the country of the people called Boii and Senones; and on the south-west washed by a portion of the Mediterranean sea, called Mare Tuscum, or Tyrrheum, the Tyrrhenian sea. This country was once more extensive than the present Tuscany, as it reached as far as the Tiber. The inhabitants of Etruria, who for a long time possessed a great part of Italy, were denominated Tusci or Etrusci. (See ETRUSCI.) The principal rivers of this country were the Arnus, the Umbro, the Clanis, and the Tiber. The chief lakes were the Lacus Trasimanus, and Vulturnensis. Among the most considerable cities we may reckon Luna, Pisa, Luca, Pittozia, Florentia, Fesulae, Portus Herculis, Labronis, Voluterræ, Sena Julia, Arretium, Cortona, Perugia, Clusium, Vetularii, &c. &c.

ETRURIA, in *Geography*, a country situated between the Mediterranean, the Tiber, and the Apennines; bounded on the east by the dominions of the pope, on the north and north-east by the kingdom of Italy, on the west by the republic of Lucca, and on the south-west by the Mediterranean; about 115 miles in length, and 80 in breadth. The face of this country is beautifully varied with hills and valleys, and the soil which is rich and fertile produces abundance of corn, and excellent fruit, oranges, lemons, olives and grapes. The air is in several parts rendered insalubrious by fens and morasses; the salt-pits are rich. Manna is gathered in the marsh-lands near the sea; and the mountainous parts are rich in mines and minerals. Several medicinal springs have been discovered besides those of Pisa. Arno is the principal river; and Florence is the capital. After several revolutions, Etruria became a republic, and deriving its name from its capital, was called Florence. And in this republic the Medici family obtained by commerce the wealth and rank of princes. It was also denominated *Tuscany*, which see; and in 1569, Cosmo I. was declared duke of Tuscany by pope Pius V., which title was ratified by the emperor Maximilian II. in the year 1575, on condition of his enjoying and holding it as a fief

of the empire. By the fifth article of the quadruple alliance, made in 1718, it was stipulated that, with the consent of the Germanic body, the emperor should confer it as a fief on the king of Spain's eldest son by the second marriage, and that it should devolve to his male descendants, and on their failure to the younger brother and his heirs. In 1737 the duchy of Tuscany became annexed to the house of Austria. By the fifth article of the treaty of Luneville in 1801, the duchy of Tuscany was ceded to the duke of Parma, and erected into a kingdom, under the name of Etruria. It has since been annexed to the kingdom of Italy.

ETRUSCA TERRA, in the *Materia Medica*, a kind of bole of which there are two species, the white and the red; these are called by many authors the *terra figillata alba* & *rubra magni ducis*, as they are brought to us sealed with different impressions.

The *white Tuscan earth* is a dense and compact substance of a dull deadish white, which in drying acquires some degree of yellowness; it is of a smooth surface, and does not stain the fingers in handling. It is not easily broken, and but slightly adheres to the tongue, and freely melts into a substance like butter in the mouth. It makes a slight effervescence with acid menstruums.

The *red Tuscan earth* is a pure bole, very heavy, and of a compact texture, and of a dull brownish red colour. It is naturally of a smooth surface, breaks easily between the fingers, and does not stain the hands; it adheres strongly to the tongue, and melts freely in the mouth, and has a strong astringent taste, and leaves no sandy harshness between the teeth. It makes an effervescence with acid menstrua. This is made up of small flat cakes, and impressed with a shield bearing a ducal coronet, &c. These are the characters by which both these earths may be known from others of the same colour: they are both dug in several parts of Italy, particularly in the neighbourhood of Florence: they are kept in the shops there, and prescribed with success in fevers of many kinds, and in diarrhœas, dysenteries, and the like cases.

ETRUSCI, ETRUSCANS, in *Ancient Geography*, a people of Italy, who inhabited that part which is now called Tuscany; though it was formerly much more extensive under the name of *Etruria*. The Etruscans, in very ancient times, are supposed to have been masters of almost all Italy; for the whole region called Italia by the Latins was denominated by the more ancient Greeks Tyrrhenia, according to Dionysius Halicarnassensis (*Antiq. Rom. lib. i.*); whence it is inferred, that it was formerly subject to the Tyrrhenians, or Etruscans, and from them received that denomination. Livy and Plutarch intimate, that the seas, which partly surround Italy, *viz.* the Tyrrhenian, Ionian, and Adriatic, were anciently denominated the Etruscan sea; and that the Etruscans possessed the whole large tract extending from the Alps to the straits separating Italy from Sicily. They built twelve cities beyond the Tiber, which were afterwards the boundary of Etruria Proper on one side; and they were the founders of Nola and Capua, and possessed twelve capital cities in the tract terminated by the Po and the Alps. Virgil and Silius Italicus rank Cæsena and Mantua among the cities of Etruscan extraction; and we learn from Livy, that this ancient nation in very early times occupied the whole tract between the Alps and the Apennines. According to Pliny, Bononia, or Bologne, was anciently regarded as the principal city of Etruria; and we may observe, that many Etruscan relics and fragments of antiquity have been dug up in various provinces of the kingdom

dom of Naples, Verona, Padua, &c. as well as the duchy of Tuscany, or the Proper Etruria. The kingdom of Latium was probably a colony of the Etruscans; and the first traces of the city of Rome may possibly have been owing to that nation. However, in process of time, the Gauls made several irruptions into Etruria, and seized upon that part of it which lay between the Alps and the Apennines. The first of these irruptions happened about 600 years B.C. and the last a little before the taking of Rome by Brennus. Several colonies of Greeks made settlements in the superior part of Etruria; and from them it was denominated Magna Græcia. The Etruscans were likewise dispossessed of a large extent of territory by the Samnites and Ligurians, long before they submitted to the Romans; so that at last they found themselves confined within the limits of Etruria Propria, where for several ages they made a very considerable figure. Etruria was called by the most ancient Greeks Tyrſenia; but Polybius, and those who lived after him, denominated this country Tyrrhenia. Tyrſenia is said to be the true name, as it corresponds with that of the Lydian prince, Tyrſenus, under whose conduct, according to Herodotus, the Tyrſeni, or Tyrrheni, first made a settlement in Italy. Etruria was divided into twelve states or dynasties, each of which had its peculiar city. Each state or tribe was governed by its own prince, called in the Etruscan language "Lucumo," and received its denomination from the capital city. See ETRURIA.

The Tyrſeni, or Etruscans, were a branch of the Pelasgi, that migrated into Europe, according to Dionysius Halicarnassensis, not many ages after the dispersion. Those who marched by land as far as Lydia detached a colony under the conduct of Tyrſenus to Italy. This colony seems to have been joined by a body of Pelasgi, previously settled in some of the islands of the Archipelago. Hence some have concluded that the Lydian Pelasgi, or Etruscans, conducted by Tyrſenus into Italy, and the first Pelasgi that inhabited Greece, were the same people; but Dionysius Halicarnassensis makes the Tyrſenians and Pelasgi two different nations. The Etruscans denominated themselves Rafeni, from their leader Rafan, or Rafen; and Tyrſenus, or Tyrſen, is said to be only the name Refen, with the ferule letter T superadded. This circumstance serves to evince, not only that the Etruscan name of the people under consideration agreed with that of the Greeks, but likewise that they were both of oriental extraction. See PELASGI.

The Etruscans seem to have derived their appellation from Etruri, or Etruri, as they were anciently denominated; and that this appellation was deduced from Athuria, or Aturia, that of their parental country, may be proved from Dionysius Halicarnassensis, Strabo, and Dio. Moreover, Aturia and Assyria differ merely in dialect; the former being equivalent to the Chaldean word אַתּוּרִיָּא, and the latter to the Hebrew אֲשׁוּר, as may be evinced from Bochart (Phaleg. l. ii. c. 3.) and others. Since, therefore, nothing is more frequent than the permutation of A and E in oriental words, especially when written in Greek letters, Atura and Etura must be regarded as the same word, and as the ancient name of Etruria. More especially if we consider that Refen was a city of Aturia or Assyria, whence, probably, the leaders of the Etrurian or Etruscan colony were denominated Rafeni, or Refeni; and that, from the sacred historian, we may conclude Ashur to have been the brother of Lud, or great ancestor of the Lydians. The term Tusci, or Thufci, is of a later date, and seems to have been given to the Etruscans by the Greeks. The sacrifices, or use of frankincense, that prevailed among the Tuscans in after ages, probably suggested this appellation to that people.

As each of the twelve tribes, or cantons, called in the Tuscan language "Lucumonia," was governed by its own prince, a king presided over the whole; and whilst the lucumo assumed the administration of affairs in his own province, the king was consulted on all extraordinary occasions, and convened the general diet of the twelve nations on all pressing emergencies. This diet was held at the temple of Voltumna, which was a celebrated city of Etruria, seated on the spot which is occupied, according to Cluverius, by the present city of Viterbo; and in this temple measures were concerted for making war upon, or concluding peace with their neighbours. Although the power of each lucumo was limited, the Etruscan kings seem to have been vested with a sort of absolute authority, consonant to the first oriental form of government.

Some of the principal Tuscan laws were such as follow: 1. By the original constitution of Etruria, no single state, or lucumonia, could enter upon a war, or conclude a peace, with any neighbouring power, without the participation of the whole Etruscan body. 2. The Etruscans, by a particular law (Athen. Deipnos. l. i. p. 23.) admitted their women to all nocturnal entertainments; in which they were afterwards followed by the Romans. 3. They obliged themselves to treat all foreigners with the utmost humanity. 4. They gave all possible encouragement, as it should seem, by virtue of their constitution, to all polite arts and artificers. 5. In order to deter people from contracting larger debts than they were able to pay, the Tuscan boys, by way of ridicule, followed all insolvent debtors with an empty purse. 6. They must have had many good moral institutions, since from them the Romans received a supplement to their Twelve Tables. 7. The jura feccialia were first observed by the Etruscans. 8. The Etruscan polity, in general, seems to have been founded upon maxims of the most consummate wisdom, as may be collected from Aristotle, and Heraclides Ponticus in Athenæus's Deipnos; to which the curious reader may be referred for further information.

The religion of the Etruscans was a gross and multifarious idolatry. In common with the ancient Greeks, and Phœnicians, they worshipped the Cabiri, or Dii magni majorum gentium. They were also initiated in the Samothracian or Cabirian mysteries.

Besides the Greek and Roman deities, they had several peculiar to themselves; some of which were confined to particular towns or districts. The divine service and sacred mysteries of the old Etruscans agreed, in several points, with those of the Greeks, but in others differed from them, and these they communicated to the Romans long before that nation had any intercourse with the Greeks. The festivals, holy days, and stated times of public worship of the Romans and Etruscans, must also have agreed in several particulars, as the Romans, before they became acquainted with the Greeks, received every thing relating to religion, and even their calendar itself, from the Etruscans. The latter borrowed of the Egyptians, or rather the Phœnician shepherds expelled Egypt, their public supplications, pœnps, and solemn processions, which occurred in some of their principal festivals. The rites and ceremonies used by the haruspices, augurs, and pontifices at Rome, were derived from the Etruscans, who seem to have been the most celebrated nation in the Pagan world for skill in augury, and divination, as well as knowledge of the nature of sacrifices, to which all rites and ceremonies necessarily relate. This, however, was their character among the Romans, as Cicero and Livy have testified. Hence this branch of science was emphatically styled at Rome "Ars Etrusca," and "Disciplina Etrusca;" so that Etruria was denominated by Ar-

nobis the mother of superstition. It is observable, that neither the Etruscans nor the Romans had any magnificent temples in the earlier ages. The Etruscans had some peculiarities in their religion, which distinguished it from that of every other nation; but the ancient Egyptian and Phœnician modes of worship were the same with those, for many of the earliest ages, used in Etruria; nor can any material difference be found between the oldest oriental and Etruscan divinities. With regard to the theological notions of the Etruscans, they believed one supreme Being, whom they called Jave, or Jove; they considered him as the great governor of the universe, as the principle of life and motion. They were firmly persuaded of the immortality of the soul, and therefore believed a future state of rewards and punishments; though in later times they seem to have followed the system of Pythagoras, and consequently to have adopted the metempsychosis of that philosopher. However, the generality of the Tuscans adhered to the Sabian superstition, in common with most of the inhabitants of the East.

The Etruscan language must have been the same, or nearly so, with the Hebrew and Phœnician. The first Pelasgic settlements in Etruria could not have taken place many centuries after the deluge, and very few after the dispersion; and at that time the languages, or rather dialects of the Egyptians, Assyrians, Babylonians, Celtes, Syrians, and Arabs, must have approached extremely near to the Hebrew and Phœnician, which the learned allow to have been almost the same. In short both sacred and profane history concur in shewing the Hebrew, Phœnician, and Etruscan tongues to have been, in the earlier ages, nearly the same. This also appears from the letters and manner of writing anciently used in Etruria. The letters are almost the same with those of the earliest Greeks, brought by Cadmus out of Phœnicia. The manner of writing is purely oriental, the letters being drawn from the right hand to the left, agreeably to the practice of the eastern nations. The former point is rendered indisputable by the Eugubian tables, in conjunction with the Sigæan inscription; and the latter by merely perusing the Etruscan inscriptions. The very remote antiquity of the first colonies that settled in Etruria, as well as of the Etruscan language and alphabet, may be easily inferred from these inscriptions; for as the Pelasgic alphabet, that prevailed in Greece before the age of Deucalion, consisted of sixteen letters, the Etruscan or Pelasgic alphabet, first brought into Italy, composed only of thirteen letters, must have preceded the reign of that prince. The high, and indeed the almost incredible antiquity of the Etruscan language and alphabet, has been clearly evinced in two dissertations, printed at Oxford in the year 1746. For other particulars relating to this subject, we refer to Dempster's "Etruria regalis," Gori in his "Museum Etruscum," published at Florence in 1737; M. Bourguet's Dissertation published in 1733, and Buonarota's of Florence in 1726; and Swinton's Etruscan alphabet, published at Oxford; and for an abstract, *Anc. Un. Hist.* vol. xviii.

The Etruscans were extremely well versed in all the arts of war and peace, and from them the Romans derived those arts and sciences that paved the way to the empire of the world. In the best ages of Rome, the Romans imitated the Etruscans; nevertheless, in after-ages the Etruscans became thoroughly debauched both in principle and practice. Augury, and every kind of divination; all the principal religious institutions, temples, statues of gods and heroes, the manner of forming or building cities, fortifications, consecrations, and nuptial rites were transmitted to the Romans by the Etruscans. Every thing also that bore any relation to civil

government at Rome, such as ensigns of royalty, the distinction of nobles from plebeians, the securæ and fasces, the lictors, &c. was derived from the same source. Arms, instruments of military music, military accoutrements and decorations, trophies, triumphs, chariots, crowns, &c. and in short every thing belonging to the art of war, or military exercises, that prevailed at Rome, were brought from Etruria. This was also the case with respect to money, locks and keys, lamps, candlesticks, glasses, cups, drinking vessels, together with the laws and customs relating to banquets and entertainments. Agriculture, planting of vines, all instruments requisite in husbandry, mills, architecture, music, and a variety of musical instruments, many sorts of diversions, especially tragedies, various kinds of garments, and even the rudiments of physic, seem to have been introduced into Italy by the Etruscans. Scenical amusements, masks, pantomimes, wrestlers, the custom of anointing their bodies, the use of wool, plastic statuary, the fabulæ œscæ or Atellanæ, nuptial verses, or versus Fescenini, and the art of making earthenware, were also derived from the Etruscans. The art of constructing ships and of navigating them, the method of equipping fleets, and all kinds of naval armaments, were known to the Etruscans before the time of Romulus; and hence we may conclude, that this nation must have been a maritime power, and that it must have possessed an extensive commerce in the earlier ages of the world. The Etruscans, who were followers of Pythagoras, and who cultivated the principles of the Italian philosophy, must have cultivated the art of music and poetry, and must have been well versed in natural philosophy and astronomy. Tragedy is said to have owed its birth to this nation; or at least they first communicated it to the Romans. The first actors who appeared upon the stage of Rome were sent for from Etruria. Besides, the ancient Etruscans, valuing themselves upon being the disciples of Pythagoras, could not be strangers to geometry, nor indeed to any of the mathematical sciences. For military learning they were famous, and especially for the art of drawing up an army, and making dispositions for an engagement. Athenæus informs us, that the formation of the phalanx, and manner of fighting consequent upon it, was invented by the Etruscans, or at least borrowed from them by the Romans. To all the other branches of literature and science for which the Etruscans were distinguished, we may add that they excelled in the knowledge and composition of history.

The first person who fixed monarchical government in Etruria was Janus, supposed by some to be the Javan of scripture, or one of his posterity, and in subsequent ages deified by his subjects as a singular benefactor. The history of their succeeding kings is intermixed with much fable, and, of course, very obscure and uncertain. It appears, however, that they were a maritime power in the time of the Argonauts; and that they commanded respect as such at least a generation before the Trojan war, and made a figure at sea before the Greeks. That the Etruscans were a powerful and polished nation, when Romulus founded or rather restored Rome, appears from some approved authors. That prince could not carry the design he had formed into execution, without the assistance of the Etruscans. From them he derived all his civil and religious institutions. *Anc. Un. Hist.* vol. xviii.

ETSED, in *Geography*, a town of Hungary, 40 miles N.W. of Zatmar. N. lat. 48° 2'. E. long. 21° 51'.

ETTENHIEM, a town of Germany, in the bishopric of Strasburg; 12 miles S.S.E. of Strasburg.

ETTENSTATT, a town of Germany, in the principality of Anspach; 5 miles N.E. of Weiffenburg.

ETTERSCHAUSEN, a town of Germany, in the principality of Wurzburg; 3 miles N. of Volckach.

ETTLSTORFF, a town of the archduchy of Austria; 9 miles W. of Sonneberg.

ETTRICK, a river of Scotland, which originates in the S.W. angle of the shire of Selkirk, and runs N.E. augmented by many small streams in its progress through a pleasant valley to the Tweed, into which it falls near Sunderland-hall,  $1\frac{1}{2}$  mile below Selkirk. The banks of this river were formerly shaded with woods, whence the county obtained the name of Ettrick forest.

ETUEND, a mountain of Persia, in the province of Irak; 60 miles S.E. of Hamadan.

ETYMOLOGICON, is used for a book, containing the etymologies of many languages. See ETYMOLOGY.

ETYMOLOGY, (from the Greek *ετυμος*, true, and *λογος*, a word,) means a true or real account of words: and as this true account is obtained by tracing them to their origin, etymology hence signifies that part of grammar which teaches the derivation of words.

Etymology is an essential and useful branch of philology; but from partial views, and an inattention to the principles which it implies, it is regarded by many as the fruitless study of words, in which neither knowledge nor certainty is attained. In order to limit, as much as possible, the province of etymology, and to remove the objections which have been made against it, we shall here briefly state the laws which direct, and the considerations which give it the precision and the fixedness of a science.

1. Etymology implies a due attention to the structure of the vocal organs, or to the affinities of elementary sounds. All men have the same organs of speech, and the same letters are founded by a similar modification of those organs. Letters pronounced by the same organs, or the same parts of the mouth, approximate in sound to each other, and from this consideration become more easily corrupted and changed one for another. Thus all the vowels, whatever peculiarity in character and sound they present to a person familiar with them, have yet a closer affinity to each other than to other letters; and hence are even interchanged. The more modern art of printing, indeed, has contributed to fix the fluctuating sounds of the vowels, by uniformly presenting them to the eye under distinct characters; but still in an etymological view they are utterly to be disregarded, or to be regarded only as one capricious, ever fluctuating impulse of the voice.

The justness of these observations will immediately appear to any one who considers those words in Latin, which are evidently derived from the Greek; or those in French and in Italian, which are derived from the Latin; or those in modern English, which are borrowed from the Gothic and Saxon tongues, and are still farther diversified in the Scotch, Irish, and Welsh dialects.

While the vowels form, as it were, the ever corrupting flesh, or the ever varying complexion of language, the consonants are the sinews and bones which impart to it strength and firmness, and which alone render it a subject of philological investigation. But the consonants have a closer alliance to some than to other letters; and their affinity depends on the manner in which they are enunciated. Thus, *p, b, f, v, w, m, or φ* in Greek, are kindred letters, being produced principally by the lips, and are therefore often changed one for another, as caprice or custom shall dictate. The same observation holds in regard to the letters *s, t, d, r, l*, which being produced by the tongue, impressed in various degrees on the extremity of the upper teeth, are called *dentals*; to those which are produced by the tongue and the

roof of the mouth and the palate, such as *g, j, z, ch*, and finally to the gutturals, which, though they exist not in our tongue, form an important class of letters in most other languages. To this distribution of the consonants into *labials, dentals, palatines, and gutturals*, the scientific etymologist will pay a strict attention, and observation will soon teach him that, however perfect any alphabet may be in regard to etymology, each class is but a variation of the same letter.

2. Etymology supposes a strict attention to be paid to *analogy*, that is, to those general principles by which any language is formed in regard to its internal structure, to the distinguishing terminations of its nouns and verbs, to its general mode of combining words, and to those changes which words usually undergo after they have been imported and naturalized, as it were, from any foreign tongue. In order to discover the nativity and parentage of any term, we must, as it were, strip it of the dress with which the custom of the country has clothed it, and we can trace it to its true origin, only when we view it separated from the termination by which it is disguised: thus *μηνη*, when imported into English, appears under the form of *moon*, having dropped *n*, its peculiar termination; and when expressing that period of time which comprehends one revolution of the moon, it assumes the termination *th*, which the analogy of the language hath warranted *month*; while in Latin it exists in the shape of *men-sis*. And here it is to be observed, that the general principles of analogy, as in natural philosophy, so in etymology, are to be collected by *induction* from instances that are simple, unequivocal, and definite, and then applied to words that are not so. The propriety and justice of these remarks it will be necessary to illustrate by a few examples.

Suppose we were asked the derivation of *οινος*, wine, *ου*, or *i*, self; *αυτοσυνα*, to rule, in Greek; we should be able to ascertain this only by unfolding a general principle in the structure of that language. The oriental tongues, to which the Greek owes its origin, abound with gutturals, which by degrees softened down into an aspirate in many of those words derived from them; while in others they melted into simple vowels, or were replaced by a labial, such as *φ, f, b, v*, or *w*. Thus *קֵה*, *khee*, life, self, became *ου*; *קֵהן*, *khaan*, a king, *αυτοσυνα*, to rule, and *יֵה*, *yeen*, *οινος*. In these derivations our conviction would be complete, because it is justified by a general principle that holds in a thousand other instances.

Suppose, farther, we were asked what were the origin of the Latin *vicus*, a village; *video*, to see; *vinum*, wine; *ovis*, a sheep; or of *wheel*, *year*, *well*, *weal*, in our own tongue; we answer that the substitution of a labial for an aspirate or a guttural, or a diphthong, forms a general principle which pervades the Latin tongue in its formation from the Greek. Hence *vicus* is from *οικος*; *vinum* from *οινος*; *ovis*, from *ου*; *video* from *εδο*. With respect to our own language a similar analogy obtains, which has converted a guttural into a labial; thus *laugh* is pronounced *lass*; *enough*, *enuff*; and most of those words which begin or end with *y* and *w*, whether derived from Hebrew, Greek, or Gothic, began or ended with a guttural. On this general principle *year* may safely be said to be derived directly or indirectly from *κυρος*, a circle, and means a period or revolution of time; *wheel*, from *ωδω*, to roll; *well*, from *קֵה*, *geel*, a fountain; and *weal* from *קֵה*, *kheel*, strength, which also has given birth to the words *beal*, and *health*.

Moreover, if we were asked the origin of *sperno*, to despise, we should say that it comes from *πτερον*, the beel, for the prefixing of the letter *s* to Greek words is a principle that pervades the Latin tongue; thus the primary sense of *sperno*,

is to put the heel upon; on the same principle is *salio*, *insilio*, *insult*, taken from ἀλλομαι. The French generally drop the gutturals either in the middle or at the end of words; hence we should be justified by an invariable analogy in saying, that *eau*, *water*, is from *aqua*, and *seul* from *singulus*. The Italians generally drop the liquid *l*; agreeably to this custom of the language, *fiume* is derived from *flumen*, a *stream*, and *piano* from *planus*, a *plain*. In German most of those words which have *t* in English are used with an *s*; as *waser*, *water*; *besser*, *better*; *es*, *it*: and the corruption of *m* into *f*, or *v*, is a principle that runs through the Welsh tongue; thus, *ve*, *voer*, and *wayr*, are but the Latin words *me*, *mare*, and *major*.

3. Etymology, in order to claim its proper rank as a branch of science, requires a strict attention to the *association of ideas*, the great law which regulates the human mind. The opinions and customs of men, it is well known, greatly influence their language; and this influence is produced by the secret and unerring impulse of association; and the reason why this branch of philology has been so much abused or called in question, is, that little or no regard has been hitherto paid to its connection with that grand invariable principle which governs the human understanding. He who attempts at etymology in any language must know the philosophical, the religious, and the political notions of the people who use it; he must be acquainted even with the physical peculiarities of their country, and from an acquaintance with the laws of the human mind he should be able to trace the secret process by which those circumstances influence their speech. We will give a few examples in illustration of these remarks.

In the early ages of the world, the principal idea under which the character of *God* presented itself was that of *superior power*; and, accordingly, the feelings which it awakened in the beholder were chiefly those of *fear*. And even the Jews, who had far more rational notions of the Deity than the Gentiles, apprehended that no one could see *God* and live. Accordingly most of those names, which signify a god, are in Greek either immediately derived from a word which signifies *fear*, or both from a common origin; thus, from אֱלֹהִים, *baab*, the first principle of things, are taken θεοί, gods; and φόβος, *fear*; τερρῶς, *terror*, owes its origin to the Chaldean תֵּרַח, *Terph*, a household god. Παν, the god *Pan*, is only the Hebrew פֶּן, *pon*, *conspiration*; δαίμων is the god of *terror*, and hence δαίμων, an invisible spirit, which was an object of *fear*, and δαιμονισμῶν, the fear of the demons, religion. It was the common notion that those demons produced violent passions and disorders in the mind and body: hence came the verb δαιμονίζω, to be mad. It was thought, too, that they were the agents of *God* in presiding over men; hence εὐδαιμων, one who had a good demon for his guardian angel, and κακοδαιμων, one who had an evil one.

The introduction of evil into the creation could not be accounted for by the heathen philosophers, only by supposing the existence of two principles equal in power, and opposite in character and operation. The good principle they naturally assimilated to the *sun*, the most splendid body in nature, whilst the evil they called *darkness*; hence the saying *God is light*: אֵל, is pronounced by the Persians *tee*, but by the Arabians *dee*, or *ideio*, *light*; hence ζῆν, from the former mode of pronunciation, and *deio*; from the latter. On this principle the Chaldean אִין, *aza*, to make hot, the action of the sun, gave birth to אֵל, to worship, or reverence. The general opinion among the philosophers was that water is the first principle of things. Hence the Arabic *mao* came, in Persian, with little variation, to signify *fruit*, *wine*, and in

Greek, *μασα*, the goddess of birth, and in English the producing month, *May*. The same word in Hebrew, by assuming *t* after the analogy of feminine nouns, is מוֹת, *mot*, *death*, which means *resolution into water*; hence the Egyptian *mot*, (whence *Moses* is supposed to have been taken,) and *mud*, what is washed together by water, just as *lutum*, *clay*, is the supine of *lavo*, or *luo*, to wash.

In eastern countries, where the heat of the sun is violent and long continued, rain is deemed the greatest blessing, and all the terms expressive, in most of the Asiatic tongues, of plenty, success, and joy, are generally borrowed from the names of water; hence the Hebrew בֵּרַךְ, *berck*, to bless; in Greek is βρέχω, to rain; in Latin *precor*, to ask for blessing, *parco*, to give blessing; *spare*, and *spargo*, to shed as the dew, or scatter as seed. The same root exists in English in the form of *brook*, the effect of rain.

4. Etymology, in order to become a rational study, implies an extensive and an accurate acquaintance with languages. It is not sufficient to be acquainted with Latin to know Greek; nor to know Italian to be acquainted with Latin, nor to know English to be acquainted with the Saxon or Gothic; but to be a good etymologist in either of these, a man must comprehend them all. So manifold is the intercommunity between all languages, that no language exists derived from one and the same source. Words exist in English which exist also in most other tongues, under differences of character and termination; and they are derived not from each other, but from a common origin; and a scientific etymologist, instead of deriving them from each other, will trace them all till they meet in a few primitive terms. It would probably be wrong, or at least it would be very doubtful to say, that *hand* comes from the Latin obsolete *hendo*, to catch with the hand, or from χερς, the parent of *hendo*, but it would be right to say that these are connate, or kindred terms, sprung, if not from each other, from some common root. In Hebrew, Persian, and Arabic אֶבֶן, *capb*, is the hand. The action of this is two-fold, as it imparts, or as it receives. In the former sense it gave birth to the Saxon or Gothic *giff*, and hence *if*; in the latter to *capio*. To take in hand is to begin a thing; hence the same word exists in the form of *Capio*; and passing into Greece it produced *καπη*, a handle.

And here it is obvious to remark, that as the root, passing into different countries, produces as it were new branches; those branches will not continue long till they in their turn become the stems of more numerous and diversified shoots; and as they thus multiply by accident, the progress of knowledge, the multiplication and distinction of ideas attendant thereon, seize, as it were, these wild and promiscuous offspring, and give them the sanction of custom, the supreme arbiter of speech, thus considering as genuine, words which at first were mere corruptions. Thus in our own tongue *gust* is wind; hence *ghost*, what consists of wind, *spectre*, a *ghast*, *ghostly*, like a *spectre*, and *gas*, an aeriform fluid, so denominated from *ghost*, first by Van Helmont. Thus also in Latin, from *πνυω*, to join together, is *pango*, to fasten, *paco*, to unite in concord, *pacify*. To paint is to fasten adventitious colours on a thing; hence *pingo*, and to give to falsehood the adventitious colours of truth is *fingo*, to feign. Again, from *μενος* is *men's mind*, *force*, *essence*, *memini*, to call to mind, *mones*, to put in mind; *manus*, *force*, or that organ in which the strength of the human body chiefly consists, *manes*, the souls or departed spirits, spirit being the essence of man; and *maneo*, to exist, the soul being that which exists after the destruction of the body.

Etymology, then, to be raised above the caprice of fruitless study, and to be classed among the useful and solid branches

branches of science, must be founded on a just regard to the affinities of letters, and to the structure of the organs of speech. It supposes an acquaintance with the philosophy of the human mind; with the analogies which form and distinguish each language; with the history of mankind, philological, religious, and political. From these, its qualifications, results its utility as a department of human knowledge. Etymology, it is evident, furnishes the readiest and most effectual means to acquire the knowledge of language; and as language is but the dress of our ideas, it holds up a mirror to delineate and reflect the operations of the human mind. It helps to ascertain the positions of ancient places, to clear obscurities in the antiquities of nations and families. What is more, when confined within its proper limits, and pursued to its full extent, it will throw much light and additional evidence on the truth of the Mosaic history, respecting the origin and propagation of mankind.

EU, or Eo, in *Geography*. See Eo.

Eu, a sea-port town of France, and chief place of a canton, in the department of the Lower Seine, and district of Dieppe, seated on the Bresse, near the coast of the English channel; 15 miles N. of Dieppe. The place contains 3400 and the canton 12,810 inhabitants, on a territorial extent of 182½ kilometres; and in 27 communes.

EVA, in *Ancient Geography*, a town of the Peloponnesus, in Arcadia.—Also, a hill of the Peloponnesus, in Laconia, near Sellasia. Polybius.

EVACUANTS, in *Medicine*, are those remedies which operate by diminishing the quantity of fluids in the body. This effect may be produced either directly, by an artificial opening into the vessels or cavities containing the fluid to be evacuated; as by blood-letting, by means of the lancet, or by cupping; by tapping; &c. Or the evacuation may be accomplished indirectly, by exciting the action of the vessels, which are naturally destined to throw off redundant fluids, on the one hand; or by producing inflammation, and a consequent discharge of fluids, from parts not naturally secreting them. Evacuants acting upon the natural emunctories, as the organs of excretion have been called, are of various quality and denomination, according to the parts upon which their action is exerted: thus, some stimulate the vessels which open into the cavity of the intestines, and carry off the fluids by stool, and are called *purgatives*, *laxatives*, or *CATHARTICS*; others excite the vessels of the kidneys to increased action, and are denominated *DIURETICS*; others augment the perspiration, and are termed *DIAPHORETICS* and *sudorifics*; others again stimulate the salivary glands, and produce a great discharge of saliva, whence they are called *SIALOGOGUES*; and others excite an increased discharge of the mucus of the nostrils, and are termed *ERRHINES*. All these kinds of evacuant medicines are occasionally employed, with a view to relieve the constitution at large, or some part of the body, from an inflammatory or febrile condition; or to remove local congestions in particular organs, &c. See *BLEEDING*, *CUPPING*, and the words in capitals; under which heads the principles of the evacuation, thus variously effected, are explained.

EVACUATION, see the preceding article.

EVACUATION, in a *Military Sense*, relates to the withdrawing of troops from any fortrels or post, not besieged, but intended to be relinquished; or eventually to be dismantled. This term is sometimes erroneously used in capitulations, where it is expressed that the garrison shall evacuate within a certain number of hours. Now, as it is in almost every case, a stipulation on the part of the victors,

that they shall be put in possession of certain gates, or defences, previous to the garrison marching out; thereby securing every advantage that may have been obtained; it stands to reason, that the term evacuation is incorrectly applied. We have, indeed, but rarely instances wherein it is properly introduced; one very recent case is however very prominent; namely, the evacuation of certain fortresses in Prussia by the French troops; for, if we are correctly informed, the Prussian forces did not, in some instances, attempt to enter until their *friends* had completely withdrawn.

It is sometimes made a condition, that particular approaches, lines, or posts, shall be evacuated; there we see the term appropriately used; because such approaches, and lines especially, are not considered as permanent works; therefore are intended to be dismantled so soon as those who erected them should retire.

Where a place is to be evacuated under the express condition of all damages being paid for, it becomes the duty of the future possessors to be very correct in causing an enquiry to be made into all depredations and grievances, before the forces about to retire quit the place. Commis-sioners on both sides are necessary; in order that every matter may be adjusted at the moment, so as to obviate future disagreements. This appears to have been attended to when the Portuguese territory was evacuated by Junot; though we have strong reason to apprehend that great evasion, and many highly nefarious acts, were practised by the French on that occasion.

EUÆMIA, of *eu*, *well*, and *αμα*, *blood*, is used by Tremelius and some other writers, to denote a good and healthy state of the mass of blood.

EUÆMON, in *Ancient Geography*, a town of Greece, placed by Steph. Byz. in the territory of the Orchomenians.

EVAGRIUS, in *Biography*, patriarch or bishop of Constantinople, who succeeded Eudoxus in 370, and whose election was much resented by the emperor Valens. From this event commenced a cruel persecution against the Catholics, which did not terminate till the accession of Gratian to the throne. Evagrius probably died in exile during this period.

EVAGRIUS, bishop of Antioch, succeeded Paulinus in the year 389; in consequence of whose election, in opposition to Flavianus, the schism in the church of Antioch, that has been much lamented by the orthodox, was continued. However, by the influence of Siricius bishop of Rome, in the council of Capua, held in 390, Evagrius's election was approved. Two years afterwards Evagrius died, and the schism terminated. Evagrius was the friend and companion of St. Jerome, who represents him as a person of an active and ardent spirit, and as the author of various writings, which he had perused. None of these that deserve particular mention are now extant. Cave. Dupin.

EVAGRIUS, surnamed *Ponticus*, and by St. Jerome *Hyperborita*, on account of the situation of the place of his nativity near the Euxine sea, flourished near the close of the fourth century. Having been ordained deacon of Constantinople by St. Gregory Nazianzen, he was instructed by this bishop in biblical learning, and advanced to the office of his archdeacon. His person and manners recommended him to the favour of the ladies; and being suspected of an improper intimacy with the wife of a man of consequence, he was obliged to retire from Constantinople in the year 385, and to remove to some distant place. At Jerusalem he embraced the monastic life, and passed 15 years at a monastery amidst the deserts of Nitria in Egypt.

Whilst

Whilst he was in this situation he refused the episcopal dignity which was offered him by Theophilus bishop of Alexandria. He afterwards defended the opinions of Origen, and laid the foundation of the tenets which, in the course of a few years, were propagated by Pelagius and his followers. He lived to an advanced age, but the time of his death has not been ascertained. Sozomen speaks of him as a man, distinguished by his learning, judgment, and eloquence; and represents him as devout, humble, abstemious, and irreproachable in his manners. Some of his writings are found entire in the "Bibliotheca Patrum," and in "Cotelerius's Monum. Eccl. Græc.;" but fragments only of the greater number are dispersed in the works of Socrates and other authors. Socrates' Hist. Eccl. Cave. Dupin. Another monk of this name flourished among the ecclesiastical writers of the fifth century. Cave. Dupin.

EVAGRIUS, an ancient ecclesiastical historian, was born at Epiphania, a city of Syria in 536 or 537. From the study of rhetoric and the profession of an advocate, in which he acquired considerable reputation, he derived the surname of *Scholasticus*. At Antioch he lived in habits of intimacy with Gregory, patriarch of that city, and when Gregory was charged with the crime of incest, and made an appeal to the emperor and a synod, Evagrius attended him to Constantinople, where his abilities and character were held in high estimation; nor was he less respected at Antioch, the place of his customary residence. The intervals of leisure which he could gain from the public duties of the several offices which he sustained, were devoted to the composition of his "Ecclesiastical History, in 6 books," comprehending the period from the year 430 to 594, and including the events that occurred from the close of the histories of Theodoret and Socrates till the twelfth year of the emperor Mauricius. His books of "Epistles, &c." and "Panegyric Oration on Mauricius," &c. are lost. His history is, upon the whole, a work of industrious research, general information, and considerable merit; though it manifests, on the part of the author, a great degree of credulity. The writers of the Romish church extol him as the only Greek ecclesiastical historian who has maintained the doctrine of the true faith; and Photius represents his style as sometimes elegant and beautiful, often too redundant and luxuriant.

The original Greek of this history was published at Paris in 1544, in folio, by Robert Stephens; in 1612 at Geneva, in folio, accompanied with a Latin version; in 1679 by Valesius, with a new version and notes; and in 1720 this last edition was republished at Cambridge in folio, with many additional notes. Cave. Valesii Præf. Dupin.

EVANDRIA, in *Ancient Geography*, a small town of Spain, in Lusitania, according to Ptolemy; supposed to be "Talavera la Veja."

EVANDRIUS MONS, one of the seven mountains, forming the site of the city of Rome, called also mount Palatine.

EVANGELICAL *Harmony and Economy*. See the substantives.

EVANGELISTS, the inspired authors of the Gospels. See Matthew, Mark, Luke and John. The symbols of these in the order now recited, according to Jerom, are a man, a lion, a calf or ox, and an eagle. According to St. Augustine, in his interpretation of Ezekiel, ch. i. 5.—10. and Rev. iv. 7, they are a lion, a man, an ox, and an eagle.

The word is derived from the Greek, *ευαγγελιστας*, formed of *ευ*, bene, well, and *αγγελος*, angel, messenger.

The denomination evangelists was likewise given in the

ancient church to such as preached the Gospel up and down, without being attached to any particular church, being either commissioned by the apostles to instruct the nations, or of their own accord, abandoning every worldly attachment, consecrated themselves to the sacred office of preaching the Gospel.

In which sense some interpreters think it is that St. Philip, who was one of the seven deacons, is called the evangelist, in the twenty-first chapter of the Acts of the Apostles, ver. 8. Again, St. Paul writing to Timothy, Ep. ii. chap. iv. ver. 5. bids him do the work of an evangelist. The same apostle, Eph. iv. 11. ranks the evangelists after the apostles and prophets.

EVANGELISTS, in *Geography*, four small islands at the western extremity of the Straits of Magellan, near the coast of South America; three are low, and one, at some distance, appears like a hay-stack. S. lat. 52° 45'. W. long. 67° 16'.

EVANIA, in *Entomology*. See SPHEX.

EVANID, a name which some authors give to those colours which are transient, or not of long duration; as those in the rainbow, in clouds, before and after sun-set, &c.

Evavid colours are the same with those otherwise called fantastical and emphatical colours. Some authors also use the same term to express those flowers of plants whose petals fall off as soon as they are opened.

EVANS, JOHN, in *Biography*, was born at Wrexham, Denbighshire, in the year 1680. His father was one of the ejected ministers in 1662, who, on account of his non-conformity, being driven from the established church, became minister to an independent congregation at Wrexham. The son was educated with great care, and inducted to the different branches of literature necessary to qualify him for the office of the ministry, which he afterwards exercised in London, first as an assistant, and afterwards as successor to Dr. Daniel Williams. He died in the year 1730, in the fifty-first year of his age, highly esteemed by all who knew him. He had ever been eminent for piety, integrity, and public spirit; in his principles he was orthodox, but disposed to think well of, and to honour, those who differed from him, without any regard to the sentiments which they might hold. He received a diploma of doctor in divinity from the universities of Edinburgh and Aberdeen. His principal work as an author consisted of two volumes of sermons, entitled "Practical Discourses concerning the Christian Temper," which are still in considerable estimation. The celebrated Dr. Watts characterized them as "the most complete summary of those duties which make up the Christian life." Gen. Biog.

EVANS'S ISLAND, in *Geography*, a small American island, near the coast of Main. N. lat. 44° 31'. W. long. 67° 3'.

EVANSHAM, a town of America, the capital of Wythe county, in Virginia, situated on the E. side of Reedy creek, which falls into the Great Kanaway, Woods or New River. It contains a court-house, gaol, and about 25 houses; 40 miles W. by S. from Christiansburg.

EVANTES, in *Antiquity*, the priestesses of Bacchus, thus called, because in celebrating the orgia they ran about as if distracted, crying *evan, evan, ohe evan!*

The word is formed from *Ευας*, a title or appellation of Bacchus.

EUANTHI COLORES, in *Painting*, a term used by the Greeks to express what the Romans call the *floridi colores*; these were such colours as had a remarkable brightness in their works. The other duller and coarser colours the Romans called *austeri colores*, and the Greeks *bathyvi*.

Of the first sort were cinnabar, lapis armenus, chrysofolia, minium, indigo, and purpurissa, according to the Romans; but the Greeks, as we find by Dioscorides, made cinnabar one of the austere colours.

EUAPHION, (from *eu, ease*, and *αφρ, the touch*;) in *Surgery*, a medicine for the hemorrhoids, named from its gentleness. Galen.

EVAPORATION, in *Natural Philosophy*, is that process by which water and other liquids are converted into vapour or steam, an elastic fluid, and dissipated in the atmosphere. Certain solid bodies, too, are subject to a similar dissipation in air; this is usually denominated *exhalation*: but as the cause is no doubt the same in both cases, it may be properly considered under this head.

The spontaneous evaporation of water, or that which is constantly going on in a greater or less degree from all parts of the surface of the globe, has always been an interesting phenomenon to the speculative philosopher. Various hypotheses have been advanced to account for the ascent of water into the atmosphere in an invisible form, and for its subsequent descent in the form of rain; but the opinions of early writers on this subject are of little importance, as they were not acquainted with the principal facts and experiments which ought to guide us in the investigation. Aristotle seems to have ascribed the formation of vapour to the action of fire; and so far his notion was correct. Halley supposes small hollow spheres of water to be filled with a subtle elastic fluid, so as to make them specifically lighter than air; he also hints at a chemical affinity between air and water, similar to that between water and salts. Desaguliers, after having shewn the insufficiency of former hypotheses, proposes a new one; he asserts that water is capable of being converted by heat into an elastic fluid much lighter than air, and refers to the steam engine as a proof; he shews, too, that a glass vessel filled with water, and inverted in another vessel of water, and then exposed to the heat of ebullition, has its water expelled, and steam, an elastic invisible fluid, takes its place. This steam, he shews, is again condensed into water as the vessel cools. He argues that steam is  $16\frac{1}{2}$  times lighter than air, and that when formed at a low temperature it must ascend in the atmosphere till it meets with air of the same density, and there it will stop; but when accumulated, the cold condenses a portion of it into drops of water: hence clouds and rain. This notion, which goes to identify vapour in the air, with the steam or vapour of water formed by heat in a vacuum, is ingenious and apparently original, but how the vapour should ascend till it arrives at air of the same density, is not very easily conceivable: for the vapour, in ascending, must expand as the pressure is diminished, according to the established laws of elastic fluids, and therefore never can obtain the same density as the air. The vapours might indeed ascend to the top of the atmosphere, and form a distinct stratum, as some have imagined with respect to hydrogen gas. The author has extravagantly under-rated the specific gravity of steam, or aqueous vapour, which is certainly at least one-half that of atmospheric air. Upon the whole, this hypothesis was more plausible than that adopted by Halley.

As the science of chemistry gradually expanded, the phenomena of evaporation began to be considered as most nearly allied to those of chemical solution. From the year 1743 to 1766 the essays of Nollet, Franklin, Roi, Hamilton and others, tended to establish the opinion that water is taken up into the air by chemical solution, in a similar way to that in which water and other liquids dissolve salts. In the 55th vol. of the *Philosophical Transactions*, there is an essay of Professor Hamilton on evaporation, in which he in-

sists at large on the hypothesis of solution. Hot water, he observes, dissolves salts sooner and in greater quantities than cold water, and deposits a part of the same on cooling: so warm air takes up more water than cold air; but the water is deposited again when the air cools, or by the contact of a cold body, as a glass of cold water. Evaporation always produces cold; this is observed when any part of the human body is moistened with water, and the same suffered to evaporate, but still more remarkably when moistened with ether or other fluids more evaporable than water; in like manner, certain salts dissolved in water constantly produce cold. In short, the points of resemblance between evaporation and chemical solution are so numerous and striking, that the generality of philosophers seem to have adopted the idea that air possesses a chemical affinity for water, and attaches a portion of it to itself, which becomes incorporated with the elastic mass of the atmosphere, under the denomination of vapour; till cold, or some other cause, reduces it again to the state of water.

In the year 1783, Saussure of Geneva published his celebrated essays on hygrometry, in which the subject of evaporation is discussed much more largely than had been previously done. This author does not claim the merit of any new theory; for, he says, "the conversion of water into elastic vapour has been known time immemorial; the dissolution of water in air was discovered by Roi, and the vesicles, which compose fogs and clouds, were conceived by Halley, and ocularly demonstrated by Kratzenstein. But no philosopher has, I believe, clearly distinguished the different modifications of vapours: all the systematic authors have endeavoured to reduce all vapours to one and the same species, whilst in reality they exist under forms absolutely different. It had not been perceived that water, on being dissolved in the air, is converted into an elastic fluid; but I have shewn this to be the fact by the most exact experiments; and further, the precise effect which the solution of a given quantity of water in air has upon the specific gravity of the air. Finally, the laws according to which the humidity of the air varies in proportion to its condensation and rarefaction, form an entirely new subject, on which our ideas hitherto have been vague and erroneous. These, I believe, will be found to have received a satisfactory elucidation." Preface, page 10. Before we examine the conclusions of Saussure, it may be proper to advert to the facts which are alluded to above. Having procured a large glass balloon, containing  $4\frac{1}{2}$  cubic feet of air, Saussure adapted to it a manometer or instrument to measure the force of elastic fluids; the balloon being filled with air of the natural humidity, the manometer, or thermometer, and a vessel containing caustic alkali of a given weight, were all enclosed in the balloon, and confined from the action of the external air. The caustic alkali absorbed the vapour in the balloon, and the manometer shewed the diminution of elasticity consequent thereon; after the experiment was carried as far as was desired, the balloon was opened, and the increase of weight of the alkaline vessel was ascertained. Hence were derived data for calculating the influence of vapour on the elasticity of the air, and likewise the whole quantity of water in a state of vapour in a given bulk of air. This might be called the analytic experiment; but the synthetic one was also made. By enclosing a piece of wet linen of a given weight in the balloon containing air as dry as possible, along with the other instruments, the moisture of the linen evaporating increased the elasticity of the confined air a quantity which could be observed; and at the close of the experiment the loss of weight of the linen indicated the quantity of water which had been evaporated,

## EVAPORATION.

and had increased the elasticity. The two methods were thus found to corroborate each other remarkably well. The results were, that at the temperature of  $64^{\circ}$ , a quantity of extremely dry air acquires an increase of  $\frac{1}{4}$ th in elasticity in attaining extreme humidity; and *vice versa*: that a cubic foot of air takes up 10 grains of water in passing from extreme dryness to extreme humidity; and that consequently it diminishes the specific gravity of the air, as if a volume of elastic fluid, equal in weight to 10 grains, and of  $\frac{2}{3}$ ths the specific gravity of air were added to it. Of the general accuracy of these results there is no room for doubt. They form a valuable acquisition to this branch of science. One important fact was still wanting; as air was supposed to dissolve water by virtue of an affinity, it was reasonable to expect that every species of air would have its peculiar affinity, or take up a certain portion of water peculiar to itself, agreeably to what is observed in other cases of chemical saturation. Saussure ascertained this point clearly in regard to inflammable and fixed air, that is, hydrogen and carbonic acid. Both these gases were found in their pure state, and when mixed with any proportion of common air, to affect the hygrometer in the same way as common air, and to promote evaporation in the same degree. In short, there was not any appearance to indicate that they contained either less or more vapour than common air in like circumstances. Saussure found that evaporation was accelerated in proportion to the rarefaction of the air; this circumstance he accounted for by observing that the pressure of the atmosphere retards evaporation; however, upon the principle of solution, it might have been expected that the greater quantity and density of the solvent would have compensated for the greater pressure. The condensation of air, on the contrary, uniformly tends to make it deposit moisture, and retards evaporation. This he explains by observing, that the solvent power of air does not increase quite so rapidly as its density; continued condensation therefore must first saturate the air with moisture, and then make it deposit a portion. Saussure found that warm and dense air required more vapour to saturate it than cold and rare air; he was led too hastily to ascribe the solvent power of the air partly to its temperature and partly to its density; but it has since been proved that temperature alone is concerned, and the density has no effect whatever. On the head of rarefaction and condensation, Saussure adverts to a curious fact, known by every philosopher, but not satisfactorily explained by any one; namely, the abundant and instantaneous formation of a cloud or mist upon exhausting a receiver by the air-pump. As the rarefaction of air is found to promote evaporation, it appears astonishing at first sight that the air should exhibit signs of super saturation at the same instant. When the pump plate is covered with wet leathers the above appearance never fails; but the abbé Nollet found it to take place when water was totally excluded. Saussure, however, denies this to be the fact; he thinks that water must not have been excluded with sufficient care in Nollet's experiments; and affirms that from his own experience no appearance of mist was found upon exhaustion, when the pump was carefully dried. The hygrometer at the time was  $70^{\circ}$ , extreme moisture being  $100^{\circ}$ . As the two authors here appear to be at issue as to the fact, the writer of this article, from his own experience, can venture to affirm that both of them may still be correct. When care is taken to exclude water from the pump and receiver, the mist is by no means so copious as otherwise; it is also more diminutive as the air is dry or far from extreme humidity; with both these circumstances and a large receiver, no mist will appear by a moderate rate of exhaustion; but

it may always be produced by using a small receiver, and rapid exhaustion. Saussure's explanation of the fact is very inadequate, and unworthy of repetition; he further notices the dew observed on the receiver of an air-pump after letting in the air, and very justly ascribes it to the condensation of the vapour raised up into the receiver after exhaustion; the air taking in with it nearly as much vapour as it is capable of holding. Upon liberating condensed air a great mist is observed in the receiver; Saussure explains this in the same unsatisfactory manner as before, and that in one case only, namely, when the receiver contains water; but his explanation does not apply when the receiver is perfectly dry; yet the phenomenon of mist is equally apparent in that case. The true explanation is, that a great but momentary cold, of  $50^{\circ}$  or more, occasions the precipitation of vapour, both upon rarefying air and liberating condensed air. The fact has since been demonstrated by Mr. Dalton; but it was hinted at by Lambert, as quoted by Saussure, page 331.

Though Saussure does not affect to introduce any new theory on the subject of evaporation, he certainly advances some notions on the subject that were not previously held by others, especially by those who adopted the chemical solution of water in air. He says, "evaporation, properly speaking, is the result or rather the effect of the intimate union of elementary fire with water; by this union the water and fire combined form an elastic fluid specifically lighter than air, and which is peculiarly distinguished by the name of *vapour*. This vapour being formed in a vacuum, or otherwise when the heat is sufficient to give it force superior to atmospheric pressure, so as to expel the air from any vessel in which it is formed, is called *pure elastic vapour*." Page 361. This representation is, in all probability, correct, and will be generally adopted without hesitation. He proceeds: "but when the vapour cannot entirely surmount the pressure of the air, it penetrates it, mixes with it, undergoes a true solution, and may then be properly called *dissolved elastic vapour*." Page 362. Certainly the advocates for the solution of water in air cannot adopt this language. Pure elastic vapour is first formed; then by means of such force as it happens to have, which is generally small, it penetrates and mixes with the air; afterwards it is dissolved by the air; that is, the particles of air finding those compound particles of water and fire amongst them, attract them, and form triple compounds of air, water, and fire. Here the business for which solution is called in is performed before hand; for we must suppose it to be the affinity of air for water which enables the latter to rise at all against so superior a pressure. If the vapour can, by virtue of its elasticity, penetrate the air, why may it not continue there by virtue of the same elasticity? Saussure proceeds; "when afterwards the air saturated lets fall the water which it contains, this water sometimes takes the form of vesicles or bubbles; these vesicles, filled and surrounded with a subtle elastic fluid, are supported in the air, and even sometimes rise in it, by their less specific gravity. These vesicles are essentially distinct from the air, as well as from the vapour above defined; but according to custom I have arranged them in the class of vapours, and distinguished them by the name of *vesicular vapour*. Finally, when the elastic vapour, or the vesicles themselves, condense into solid drops, which only differ from drops of rain by their extreme smallness, they are still very different from vapours properly speaking. Notwithstanding, as these small particles float in the air, and can even be supported in it for some time, by its agitation and viscosity, I have classed them also amongst vapours, and given them the name of *concrete vapours*." Page

## EVAPORATION.

Page 363. It may be proper to observe here, that the vesicular vapour of Dr. Halley was supposed to be transparent, and therefore to correspond to the *dissolved elastic vapour* of Saussure. It was moreover hypothetical; but Kratzenstein and Saussure affirm that the small visible particles floating over steaming water, as well as those of certain fogs, are discernible by a microscope to be hollow or vesicular. These visible particles are the *vesicular vapour* of Saussure. Though it is by no means improbable that the vapour issuing from warm water is enveloped in a film of water, just as we see it in ebullition, and that the same bubble of steam on cooling may shrink into a vesicle, containing an atom of air, the original nucleus of the steam; yet it is not equally probable that in the condensation of pure vapour a vesicle should be formed: still less likely is it that sometimes vesicles, and at other times solid drops, should be formed. Microscopic observations on atoms dancing about in the air are scarcely to be relied on. But whatever may be the fact as to the constitution of condensed vapour, that is, whether the particles are hollow or solid, there is not any sufficient reason for supposing them constituted of any other principles than water and atmospheric air. The only one that has been advanced in support of the hypothesis is, that without some subtle elastic fluid, internal or external, the watery particles constituting clouds must constantly descend; whereas clouds are seen to remain stationary and sometimes even to ascend, which, it is alleged, could not take place, were not the particles of less specific gravity than the air. Now the ascent of clouds is in all probability an optical deception. It is occasioned by the dissolution or evaporation of the under surface of the cloud, and the superior new formation of a cloud. We have no sufficient reason for believing that the individual particles of clouds ascend; yet they frequently descend with a velocity almost imperceptible; this arises from the resistance the air makes to the motion of small bodies, which, it is well known, increases in proportion as their diameters decrease. The epithet *vapour*, which denotes an elastic fluid, cannot, with philosophical propriety, be applied to the visible particles of water constituting clouds.

Mr. Pictet of Geneva published an ingenious essay on fire, which was translated into English and published in 1791. This gentleman, impressed with such ideas of the powers of fire in every thing which relates to evaporation, is tempted to look upon it as the sole agent in this class of phenomena, and to renounce the idea that air acts in the manner of chemical *dissolvents*. He observes, "the very specious arguments of my learned colleague (Saussure,) in his hygrometry in favour of that opinion, had long seduced me; but the charming simplicity which the theory of evaporation would acquire if we could divest it of the agency of air; the possibility I perceive of reducing the whole to the action of fire; the probability which increases with the simplicity of every natural hypothesis, attract me, I confess, still more forcibly." Page 222.

In the *Philos. Transac.* for 1792, there is an essay of De Luc on evaporation. This acute philosopher distinctly maintains that vapour in the air is precisely the same as vapour in vacuo, and in both cases is formed by the intimate union of fire with water; he denominates it *steam*, and shews that steam in air of any density, and steam in vacuo, affect the hygrometer alike, provided the steam has the same temperature and elasticity, at least within the ordinary range of atmospheric temperature. He strengthens his opinion of steam in air, and in vacuo being the same from the fact that cold is produced, or heat absorbed, by evaporation in both cases. From the facts as ascertained respecting steam by Mr. Watt

and others he justly infers, that there is a certain minimum distance of the particles of steam for each temperature, at which they retain their elasticity; if they are condensed by any mechanical force within the limit of this distance, they lose their elasticity and become water; if not, they retain it, and act as any other permanently elastic fluid. In speaking of steam in air, he observes, "that no mechanical cause can produce the decomposition (condensation) of that fluid, but by forcing its particles to become nearer each other than the actual temperature can admit, which cannot happen in the atmosphere, except by the accumulation of steam itself in some part of it." "He concludes that the product of evaporation is always of the same nature, namely, an expansible fluid, which either alone, or mixed with air, affects the manometer by pressure, and the hygrometer by moisture, without any difference arising from the presence or absence of air, at least without any perceived hitherto."

In 1793, Mr. Dalton published a volume of meteorological essays, in which he gives a theory of vapour, very nearly allied to that of De Luc above-mentioned, and to the opinion of Pictet, though he seems to have been unacquainted with these circumstances. From the results of certain experiments and observations he concludes, "that the vapour of water (and probably of most other liquids) exists at all times in the atmosphere, and is capable of bearing any known degree of cold without a total condensation, and that the vapour so existing is one and the same thing as *steam* or vapour of 212° or upwards. The idea, therefore, that vapour cannot exist in the open atmosphere under the temperature of 212°, unless chemically combined therewith; I consider as erroneous; it has taken its rise from a supposition that *air* pressing upon vapour condenses the vapour equally with *vapour* pressing upon vapour, a supposition we have no right to assume, and which, I apprehend, will plainly appear to be contradictory to reason and unwarranted by facts; for, when a particle of vapour exists between two particles of air, let their equal and opposite pressures upon it be what they may, they cannot bring it nearer to another particle of vapour, without which no condensation can take place, all other circumstances being the same; and it has never been proved that the vapour in a receiver from which the air has been exhausted, is precipitated upon the admission of perfectly dry air. Hence then we ought to conclude, till the contrary can be proved, that the condensation of vapour exposed to the common air does not in any manner depend upon the pressure of the air." *Essays*, p. 201.

In 1802, Mr. Dalton published, in the fifth vol. of the *Manchester Memoirs*, a series of interesting essays relative to evaporation; he found, 1st. The expansive force of pure steam over water in vacuo at all temperatures from 32° to 212°; 2d. The expansive force of dry air for the same range of temperature; and, 3d. The expansive force of dry air in contact with water for the like range. From a comparison of these experiments it appeared that the observation of De Luc was universally true; namely, that steam in vacuo and steam in air are precisely of the same force at the same temperature. The law was found to apply equally to the steam from ether and other liquids, and to other elastic fluids, as well as common air. Mr. Dalton considers these facts to be decisive as to the nature of the connection between steam and air, and infers that steam forms a mechanical mixture with air, and not a chemical compound, as some have supposed. This conclusion was confirmed by experiments upon the quantity of water evaporated at different temperatures; which was always in proportion to the elastic force of vapour at the temperature. For instance, water at 212°, or kept just boiling, evaporates twice as fast as wa-

# EVAPORATION.

ter of 180°, and this twice as fast as water of 150°; and the forces of pure steam at those temperatures are 30, 15, and 7½ inches of mercury respectively. The rule, however, does not apply without a correction for low temperatures; because the steam already in the air prevents in degree the ascension of fresh steam; whereas in high temperatures, the small portion of steam commonly in the air is too trifling to have any observable effect. Mr. Dalton has given a table founded upon experience, and adapted to the above-mentioned law, by which not only the actual quantity of water evaporated in atmospheric temperatures may be ascertained, but also the quantity of vapour existing in the air may be found, provided the rate of evaporation is given. The following is an abstract of it.

The first column of the table expresses the temperature; the second, the corresponding force of vapour in vacuo, derived from experiment; the third column expresses the number of grains of water evaporated per minute, from a surface of 28¼ square inches, in a moderate current of air or nearly calm; the fourth is the like evaporation in a medium current; and the fifth is the evaporation when a strong breeze exists, or a rapid current of air sweeps over the evaporating surface. The air is supposed to be perfectly dry or free from vapour; otherwise every particular state of atmospheric vapour would require a table. The table is intended to be used when we want to find the quantity of water evaporated from a given surface by the slow and gradual operation of the atmospheric temperature, or what has been called *spontaneous* evaporation. But as it is adapted to air perfectly free from vapour, it cannot be of any practical utility without further data. The force of vapour actually existing in the atmosphere at the time must be first ascertained, by determining the temperature at which dew begins to be formed on a glass, &c. containing cold water or a cold mixture. Then the force due to that temperature must always be subtracted from the whole force due to the given temperature of the evaporating water.

Whole evaporating force, per table, for 60° = 2.70 grains.  
 Existing force of atmospheric vapour for 50° = 1.92 grains.  
 Remainder - - - = .78 grains.

Hence a surface of 28¼ inches would lose 780 dths of a grain in each minute.

Again; suppose the atmospheric vapour to be at 20°, with a strong breeze, in one case, the air being 32°; and the atmospheric vapour to be at 50°, in another case, with calm air at 58°; query the rates of evaporation in those two cases?

1st Case. Whole evaporating force per table, for 32° - - - = 1.26 grains.  
 Existing force of atmof. vap. for 20° = .82 grains.  
 Remainder, or rate of evaporation = .44 grains.

2d Case. Whole evaporating force, per table, for 58° - - - = 1.96 grains.  
 Existing force of atmof. vap. for 50° = 1.50 grains.  
 Remainder, or rate of evaporation = .46 grains.

Hence it appears that under the circumstances above-mentioned the evaporation would be nearly the same in both cases.

*Problem 2.*—Having given the rate of evaporation, to find the quantity or force of atmospheric vapour.

Suppose the evaporation from a surface of 28¼ inches is found to be one grain in a minute, with a medium breeze, the temperature being 70°; query the quantity and force of atmospheric vapour?

Whole evaporating force, per table, at 70° = 3.70 grains.  
 Observed evaporating force - - - = 1.00 grains.

Remainder = existing atmospheric force 2.70 grains, which corresponds to 60°, for the temperature at which the atmospheric vapour would be found to be condensed at the time.

Mr. Dalton contends that all the different gases constituting the atmosphere, namely, azotic, oxygenous, carbonic acid, and steam, are independent of each other; so that they press the surface of the earth and other bodies with their own weight only, when in a state of equilibrium. Whence he considers the *quantity* and *force* of steam in the atmosphere as synonymous terms. Thus in the above example, the force of steam of 60° being represented by .524 parts of an inch of mercury, the weight of the incumbent atmosphere of steam must be the same, or equal to 7 inches of water nearly. This notion, concerning the whole quantity of steam in the atmosphere incumbent upon any place, is entirely new; and, if correct, must be of the first importance in meteorology.

Though the reasons assigned by De Luc and Dalton for the non-condensation of steam, already existing in air, appear to be incontrovertible, yet from what has been said above, no sufficient reason has been given by either of them for the *entrance* of steam of low temperatures into the atmosphere. How does steam of ½th part of the force of the atmosphere at first penetrate it? Even Saussure speaks of the fact, and as if there were no difficulty attending it. De Luc does not attempt any explanation. Dalton seems to have been fully aware that the hypothesis of pure steam existing in air was not tenable without obviating this difficulty. Accordingly he conceived that the particles of steam are not repulsive to those of air, but only to other particles of steam; hence the new formed steam has a kind of vacuum, to enter in the pores or interstices of the air. But this, it is thought by many, is going into the other extreme, and

TABLE.

Temperature	Force of vapour in Inch. of Mer.	Grains of Water evaporated.		
		Lowest	Mean	Highest
212°	30.00	120	154	189
20°	.129	.52	.67	.82
25	.156	.62	.79	.97
30	.186	.74	.95	1.17
35	.221	.80	1.14	1.39
40	.263	1.05	1.35	1.65
45	.316	1.26	1.62	1.99
50	.375	1.50	1.92	2.36
55	.443	1.77	2.28	2.78
60	.524	2.10	2.70	3.30
65	.616	2.46	3.16	3.87
70	.721	2.88	3.70	4.53
75	.851	3.40	4.37	5.34
80	1.000	4.00	5.14	6.29
85	1.17	4.68	6.07	7.46

*Problem 1.*—Having given the quantity or force of atmospheric vapour, to find the rate of evaporation,—

Suppose that atmospheric vapour begins to be condensed at 50°, and the temperature of the air is 65°; query the rate of evaporation, with a medium breeze?

making the facility much too great; besides, there is no notion so general and so probable, as the one that heat is the cause of repulsion; and if this notion be true, the particles of steam cannot be admitted to be repulsive of each other, and indifferent to those of air. Mr. Dalton, it seems, now considers the inequality in the size of the ultimate particles of different elastic fluids to be the cause why they are constantly diffusing themselves through each other, and never obtain a proper equilibrium till their particles take the arrangement, which they would do in a vacuum; and the elevation of steam from the surface of water, he supposes, takes place, because certain particles of the surface are in a great measure exempt from the pressure of the atmosphere. See *New System of Chemical Philosophy*, p. 190.

From the experiments of Mr. Watt on steam, it appears that evaporation at high and low temperatures is much the same as to the expenditure of heat for a given weight of water.

The evaporation from ice of 32° does not differ materially from that of water, at the same temperature. Electricity is said to promote evaporation in some degree.

*Evaporation in Meteorology.*—With respect to the natural evaporation of water from the surface of the earth, the experiments of Mr. Hoyle and Mr. Dalton, of Manchester, are nearly the only ones that are sufficiently numerous from which to draw any conclusions. They took a cylindrical vessel of tinned iron, 10 inches in diameter, and three feet deep; there were two pipes folded into it, one at the bottom, the other at the top, for the water to run off into bottles. The vessel was filled with gravel, sand, and soil, and subsequently the soil was covered with grass and other living vegetables. It was nearly buried in the ground in an open situation, and provision made for placing bottles to the two pipes. In this manner it was exposed to receive the rain, and to suffer evaporation from the surface, the same as the surrounding green ground. A regular register was kept of the water which percolated through the soil and gravel into the bottles; and a rain gage of the same surface was kept close by, for the sake of comparison. The results are contained in the table below, together with the mean evaporation from a like surface of water, for the three succeeding years.

Water through the two Pipes.				Mean.	Mean Rain.	Mean Evap. from Ground	Mean Evap. from Water.
1795	1697	1798	Inch.				
January	Inch. 1.90	Inch. .68	Inch. 1.77	Inch. 1.45	Inch. 2.46	Inch. 1.01	Inch. 1.50
February	1.78	.92	1.12	1.27	1.80	.53	2.00
March	.43	.07	.34	.28	.90	.62	3.50
April	.22	.30	.18	.23	1.72	1.49	4.50
May	2.03	2.44	.01	1.49	4.18	2.69	4.96
June	.17	.73	—	.30	2.48	2.18	6.49
July	.15	.03	—	.06	4.15	4.09	5.63
August	—	—	.50	.17	3.55	3.38	6.06
September	—	.98	—	.33	3.28	2.95	3.90
October	—	.68	—	.23	2.90	2.67	2.35
November	—	1.04	1.59	.88	2.93	2.05	2.04
December	.20	3.08	1.88	1.72	3.20	1.48	1.50
Rain	6.88 30.63	10.95 38.79	7.39 31.26	8.41	33.55	25.14	44.43
Evap.	23.75	27.84	23.87				

From this table it appears that the evaporation from a surface of water, is nearly twice as much as from green ground; also, that about eight or nine inches of rain are left for the supply of springs and rivers. This surplus of water must be evaporated from the sea, and return to it again by the rivers.

*Evaporation in Chemistry.*—When artificial heat is applied, the quantity evaporated will be nearly in geometrical progression to the excess of temperature, above that of the air. It is always nearly in proportion to the surface exposed. When the liquid is much below the margin of the vessel, the evaporation is greatly retarded.

*Evaporation in the Arts.* In certain arts, such as dyeing, printing, &c. quick evaporation is expedient. This is effected by exposing the wet pieces in a stove, which has commonly a fire and long flues from which the heat is dissipated into the room. The cold air should be admitted into the room as near the fire and flues as possible; and several small openings at the top of the stove should be made to suffer the vapoury air to escape.

See the articles **CLOUDS, DEW, DISTILLATION, HYGROMETER, RAIN, STEAM, &c.**

*EVAPORATION, in Pharmacy, Chemistry, &c.* denotes an operation by which the more aqueous and volatile parts of fluids are spent, or driven away in steam, so as to leave the remaining part stronger, or of a higher consistence than before.

Evaporation is effected by setting a liquor over a gentle heat, to carry off the most fluid and volatile parts, without lessening the quantity of the other matters with which the liquor is impregnated.

The vessels used for this purpose are basons, tests, or crucibles, which are made of glass, metal, or earth, according to the nature of the bodies on which the operation is to be performed. They are flat, shallow, and wide, so that the body from which the evaporation is to be made may present a large surface to the air. In all evaporations the degree of heat ought to be proportioned to the volatility of the substance to be evaporated, and to the degree of fixity of the substance intended to be left, and of its adhesion to the volatile parts. In some cases, as in obtaining oil from rectified spirit of wine and ether, the liquors ought to be evaporated upon the surface of water in open air, without any other heat than that of the atmosphere; in others, when the part to be evaporated is not very volatile, and when the remaining substance is very fixed, and does not adhere much to the volatile part, as in the purification of gold by antimony, a strong heat may be applied, and a current of air directed upon the surface of the body. Macquer.

**EVARCHUS**, in *Ancient Geography*, a river of Asia, forming the boundary between Paphlagonia and Cappadocia. Valerius Flaccus assigns it to Scythia, and says it abounded with swans.

**EVARISTUS**, in *Biography*, bishop of Rome, was elected to that office about the year 100, in which he continued eight or nine years. Much has been said of him with regard to his decretals; his distribution of Rome into parishes, his presenting Adrian with a book concerning the excellence of the Christian religion, and his martyrdom under the reign of that emperor; but these and other facts collected by modern writers do not stand on sufficient authority to obtain credit. Moreri.

**EVASION, EVASIO**, in *Law*, is used for any subtle endeavour to set aside truth, or to escape the punishment of the law, which will not be endured. Thus, if a person says to another that he will not strike him, but will give

him a pot of ale to strike him first; and accordingly he strikes, the returning of it is punishable; and if the person first striking be killed, it is murder; for no man shall evade the justice of the law by such a pretence to cover his malice. Hawk. P. C. 81.

**EUASPLA**, in *Geography*, a river of India, in the northern part of the mountain Paropamisus, which ran S.E. into the Indus.

**EVATES**, a branch or division of the ancient Celtic philosophers, the Druids.

Strabo distributes the philosophers among the Britons and Gauls into three sects; Βαρδοί, *Bards*, Ουατῆς, *Evates*, and Δρυῖδες, *Druids*. He adds, that the Bards were poets and musicians; the Evates, priests and naturalists; and the Druids, moralists as well as naturalists. But Marcellinus, Vossius, and Hornius, reduce them all to two sects, viz. Bards and Druids. Lastly, Cæsar, lib. vi. comprehends them all under the name of *Druids*; which see.

The Evates or Vates of Strabo might probably be what other authors, and particularly Ammian. Marcellin. calls *Eubages*; but Mr. Bouche, in his *Hist. de Provence*, lib. ii. chap. 2. distinguishes between them. The Vates, he says, were such as took care of the sacrifices and other ceremonies of religion; and the Eubages, those who spent their time in the search and contemplation of the great mysteries of nature.

**EVAUX**, in *Geography*, a town of France, in the department of Creuse, and chief place of a canton, in the district of Aubusson; 26 miles E. of Gueret. The number of inhabitants in the place is 2,081, and in the canton 8,036, and the territorial extent of 232½ kilometres includes 12 communes. Near it are a mineral spring and baths. N. lat. 46° 10'. E. long. 3° 33'.

**EVAX**, in *Botany*, Gærtn. v. 2. 393, see **FILAGO**.

**EVAZA**, in *Ancient Geography*, an episcopal see of Asia propria, under the metropolis of Ephesus; mentioned in the acts of the council of Ephesus.

**EUBAGES**, an order of priests or philosophers among the ancient Celtæ or Gauls. Chorier takes the Eubages to be the same with the Druids and Saronidæ of Diodorus. Others will have the Eubages to be those whom Strabo, lib. iv. p. 197. calls Ουατῆς, *Evates*, or *Vates*, on which principle there is room to conjecture, that the word should be written Ουαγῆς, it being easy to mistake a Γ for a Τ. See **DRUID**.

**EUBELSTADT**, in *Geography*, a town of Germany, in the bishopric of Wurzburg, on the Maine; three miles S. of Wurzburg.

**EUBŒA**, in *Ancient Geography*, one of the most considerable of the Greek islands, formerly joined to Bœotia, as Pliny informs us, by an isthmus, so narrow is the Euripus in some places, which separates it from the continent; and extending from north-east to south-west 150 miles; but where broadest being only 40 miles, and 20 where it is narrowest. In compass it is estimated at 365 miles. This island was anciently denominated Chalcis, Ellopia, Aonia, Abantis or Abantia, Macris, Oche, Bomo, &c. Its appellation Eubœa is said to be derived from a famous cave on the eastern coast of the island, called by the Greeks αυτη βοος, or the ox stall, and this name was probably deduced from its excellent pastures. Eubœa had several remarkable promontories, which stretched far into the sea; of these Pliny and Mela mention three, viz. Gerastus and Caphareus to the south, and Cenæum to the north; and Strabo mentions a fourth, which he calls Petalia, over-against Sunium. Cenæum, now Capo Liter, and Gerastus, now Capo Rosso, are, according to Strabo, 1200 furlongs distant from each other,

which measure exactly the length of the island, as it is set down by Pliny. The mountains of Eubœa are high, and covered during a great part of the year with snow. The famous city of Chalcis was situated under one of them of the same name, and on another, called Dryphis, was a temple dedicated to Diana. The following rivers are mentioned by Strabo, viz. Callas, Budarus, Cirocæus, and Neleus or Melas. The champaign country was exceedingly fertile, and yielded great plenty of corn, wine, oil, and all sorts of delicious fruits; but it was chiefly famous for its rich pastures. This island had in former times many cities of great note, which are mentioned by Strabo, Pliny, Ptolemy, and Mela. On the eastern coast stood the cities of Gerastus, which was a famous haven, Petalia, and Carystus, near which were the celebrated quarries of Carystian marble, so much valued by the Romans, and also of Amianthus or Asbestos. About five miles from Carystus was the village of Amarynthus, famous for a temple of Diana. On the same coast stood Eretria and Chalcis, which see respectively. Between Chalcis and the promontory Cenæum, stood the cities of Edepsum and Oreos; the former being famous for its hot-baths, and the latter one of the most powerful cities of Eubœa during the Trojan war, and occupying the fourth part of the island, in the time of Philip, the father of Alexander. The name Oreos was changed by the Athenians, when they became masters of the island by means of Pericles, into that of Isthiza, or Hestiza, which was the name of their tribe. On the north side of the island, opposite Thessaly, and extending from Cenæum to Artemesium, stood Dia, or Athenæ Diadæ; and on the coast, washed by the Ægean sea, stood the maritime city of Cerinthus. The inland cities mentioned by Strabo, Pliny, Ptolemy, &c. were Ellopia, Nyfa, Eubœa, Orabiz, Rhamnus, Porthmus, Algæ, and Tamyna.

Eubœa was probably one of the islands in which the first Orientals, who passed from the continent of Asia towards the coasts of Greece, made a settlement. It must have formed a very powerful state at an early period, since its king Elphenor conducted 40 ships to the war of Troy. Solinus ascribes the commencement of this monarchy to the Titans. Others suppose Abas to have been the first sovereign of Eubœa. The succession of its sovereigns is little known. In the time of Darius Hystaspis, the cities of Chalcis, Eretria, Carystus, and Oreos, formed distinct republics, governed by the nobles, whom they called hippobates, or horsemen; none being received into the government who were not able to maintain a certain number of horses. This oligarchy was not of long duration; but it was succeeded by a democracy, composed of domestic tyrants, who seized all power to themselves, and ruled in their several cities without controul. At length the Eubœans submitted first to Philip of Macedon, and then to his son Alexander, on whose death they endeavoured to shake off the Macedonian yoke; but they were again brought under subjection by Antigonus. When the Romans first passed into Greece, the kings of Macedon held this island in subjection; but it was soon after declared free by the senate, in order to weaken the power of Philip in these parts. But not being supplied with forces, they were unable to maintain their liberty; and fell under the power of Antiochus the Great, and Mithridates king of Pontus. The Romans, however, prevailing in the East, restored the Eubœans to their former state of liberty. It was not long before Marc Antony subjected them to Athens; but Augustus, incensed against the Athenians for assisting his rival, first gave freedom to the city of Eretria, and soon after to the whole island, which remained in a flourishing condition, under its own laws, till

the reign of Vespasian, when it underwent the same fate as the other states of Greece.

**EUBŒA**, the name of several towns in the island of Eubœa, Coreyra, and Lemnos.

**EUBULIDES**, in *Biography*, a native of Miletus, was a successor of Euclid in the Megaric school. He was a strong opponent of Aristotle, and seized every occasion of censuring his writings and calumniating his character. He introduced new subtleties into the art of disputation, several of which, though often mentioned as proofs of great ingenuity, deserve only to be remembered as examples of egregious trifling. They belong to that sophistical mode of reasoning, called by Aristotle eristic syllogisms. A single specimen will be sufficient. It shall be of the sophism, called from the example, "the Lying:" if, when you speak the truth, you say you lie, you lie; but you say you lie, when you speak the truth; therefore in speaking the truth, you lie. These silly inventions for perplexing plain truth were formerly in such high repute, that Chrylippus wrote six books upon the above mentioned sophism; and Philetas, a Choan, died of a consumption which he contracted by the close study he bestowed upon it. The inscription upon his tomb was Ὁ Δεδωμένος, "The Deceived." Brucker's Hist. Phil. by Enfield, vol. i. p. 192.

**EUCALYPTUS**, in *Botany*, from *eu*, well, and *καλυπτός*, covered, alluding to the peculiar lid which covers the calyx and encloses the organs of impregnation. L'Herit. Sert. Angl. 18. Ait. Hort. Kew. v. 2. 157. Willd. Sp. Pl. v. 2. 976. Mart. Mill. Dict. v. 2. Sm. Bot. of N. Holl. 39. Juss. 451. Class and order, *Cosmofandria Monogynia*. Nat. Ord. *Hesperideæ*, Linn. *Myrti*, Juss.

Gen. Ch. Cal. Perianth superior, of one leaf, abrupt, entire, permanent, closed before impregnation with a convex or conical, entire, deciduous lid, which is sometimes, if not always, of two or three layers. Cor. none. Stam. Filaments numerous, thread-shaped, equal, inserted into the margin of the calyx within the lid, and not expanding till after it falls, anthers roundish, two-lobed, small. Pist. Germen inferior, urceolate, firmly united with the base of the calyx, sometimes angular; style simple, columnar, about as long as the full-grown stamens; stigma simple, bluntish. Peric. Capsule roundish, crowned with the rim of the calyx, of three or four cells, opening at the top. Seeds numerous, angular, small.

Ess. Ch. Calyx superior, permanent, truncated, covered before flowering with an entire lid, which soon falls off. Capsule of three or four cells, opening at the top. Seeds numerous.

This genus was founded by the late M. L'Heritier in his Sertum Anglicum, upon a single species, from Van Diemen's land, named by him *obliqua*, and figured in the 20th plate of that work. Its description never appeared. The generic characters were by him communicated to the Hortus Kewensis, and adopted, with some necessary corrections, in Dr. Smith's Botany of New Holland, where a second species is figured, *E. robusta*, t. 13. This is called New Holland Mahogany, or Brown Gum Tree, and is one of the loftiest trees about Port Jackson, being often 100 feet high, and proportionably thick. The wood hard, heavy, strong, red and very resinous. Leaves alternate, stalked, ovate, entire, a little oblique and unequal. - Flowers in dense simple umbels, of a tawny yellow, on simple or divided angular stalks, growing in a corymbose manner about the ends of the branches. The lid in this species is conical, as long as the calyx and germen, with a striature in the middle; that of the former is short and hemispherical, with a minute point. Four more species from New South

Wales are described in the work last mentioned, and six additional ones by the same author in the Transf. of the Linn. Soc. v. 3. p. 283—288. All these 12 are adopted by Willdenow in his Sp. Pl. A new one, *E. marginata*, was added to this list by Dr. Smith in Tr. of Linn. Soc. v. 6. 302, who has since figured and fully described one of the most important of the former, *E. resinifera*, the Red Gum Tree, in his Exotic Botany, v. 2. 49. t. 84. This blossomed in Lady De Clifford's greenhouse at Paddington. The flowers are green with white stamens. Lid conical, twice as long as the calyx and germen, consisting of three coats, of which the outermost is formed of three ribs originating from the angles of the germen.—The tree produces an astringent resin of a fine deep red, whose probable uses in medicine or the arts merit enquiry. Many more species of this genus are said to abound in New Holland, all lofty trees, destitute of hairiness, with simple, lanceolate, or somewhat ovate, pointed, entire leaves, generally oblique, and often unequal, at the base; without stipulas. They are commodiously divided into two sections, by their hemispherical or conical lids.

**EUCARPIA**, in *Ancient Geography*, a town of Asia, in Greater Phrygia, according to Ptolemy and Strabo.

**EUCERA**, in *Entomology*, a genus of Hymenoptera; proposed by Scopoli, and adopted by various late writers. Under this denomination are comprehended those of the Linnæan genus *Apis* (bee), which have the mandibles horny, incurvated, acute, and toothless; jaw elongated, and membranaceous at the tip; lip horny, five-cleft; tongue inflected and seven-cleft; antennæ cylindrical, those of the male very long, and often exceeding the length of the body; the abdomen short and downy; tail of the female armed with a sting. The insects of this genus form cylindrical cavities in the earth, in which they deposit their eggs, each included in a separate cell, and furnished with a suitable provision of honey for the subsistence of the young when hatched. In the winged state the Eucera fly with great rapidity, and like the bee, collect the farina and nectar of flowers with great industry and activity. The females commonly differ much in appearance from the males of the same species, independently of the length of the antennæ.

#### Species.

**LONGICORNIS**. Black; summit of the head, thorax, and two first rings of the abdomen above grey-downy; rest of the abdomen nearly glabrous. Latreille. *Eucera longicornis*, Fabr. Kirby. Ap. Angl.

Native of Europe. The female of this species is not distinctly ascertained. Mr. Kirby seems to entertain no doubt of its being the insect figured by Panzer under the name of *Andrena strigosa*. Since his observations appeared, however, Latreille has written on the same subject, and though he does not refer to the remark of Mr. Kirby, he evidently alludes to it in the following passage, "Je doute que l'andrene, que Panzer nomme *strigosa*, soit la femelle de cette espèce. Son abdomen est très-différent par ses taches de celui de *Eucere longicorne* et cet insecte ne paroît qu'au milieu du Pête, tandis que le dernier ne se voit, qu'au printemps." The difference of the abdomen may perhaps be considered in this ambiguous race less definitive than the time of its appearance in the winged state; for if the first be constantly found only in the middle of the summer, and the other in spring, we should admit them to be distinct. It further merits observation that Latreille describes an insect which he imagines to be the true female, "La femelle, &c."—"The female, or, at least, that which I regard as such, and of which I have

have seen an individual in the collection of the naturalist Baumhaaver, differs only in the shortness of the antennæ; the head entirely black, and the posterior feet very downy." The species inhabits Europe.

**ATRICORNIS.** Antennæ black, as long as the body, which is hairy and ferruginous. Fabr.  
Native of Barbary.

**GLAUCA.** Antennæ ferruginous, as long as the body, the latter hairy and glaucous. Fabr. Sp. Inf. &c.

Inhabits the East; two first segments of the abdomen with a black band.

**LINGUARIA.** Antennæ black, length of the abdomen; thorax cinereous; abdomen black. Fabr.

Native of Europe, on flowers.

**TUMULORUM.** Antennæ length of the abdomen; body black; legs and jaws yellowish. Linn. Fn. Succ. *Eucera tumulorum*, Fabr.

An European insect, also found on flowers.

**GRISESCENS.** Antennæ black, as long as the body; the latter hairy and cinereous. Fabr.

Inhabits Barbary.

**ANTENNATA.** Antennæ as long as the body; abdomen black, with whitish streaks. Fabr.

A small insect, found in abundance in the environs of Paris in autumn, and also in other parts of Europe. The lip is marked with a trilobate spot of yellow; the head and thorax cinereous; abdomen glabrous; edges of the segments fringed with white, legs testaceous.

**CURVICORNIS.** Blackish-grey; antennæ convoluted, sub-clavated; abdomen roundish; margin of the wings black. Scopoli. Native of Carniola.

**BREVICORNIS.** Ferruginous hairy; abdomen brassy; antennæ short and black. Fabr. Suppl.

This is an inhabitant of Italy, and is described by Fabricius from the cabinet of Dr. Allioni. The head, thorax, and legs with ferruginous hairs.

**CRASSIPES.** Hairy cinereous; abdomen black, with the margins of the segments greenish; posterior thighs thick. Fabr. Suppl.

Native of Tranquebar in the cabinet of Lund. The antennæ of this insect are short; the wings are dusky with fuscous tip; legs yellowish; thighs of the posterior pair thick, dentated, and black; shanks incurvated, toothed, and yellow. Whether this and the species immediately preceding ought strictly to be placed with the *Eucera*, (so named from the length of their antennæ,) if they should be of the male kind, may be submitted with deference; the sex is not mentioned in either instance. Fabricius described them as *Eucera*, and they agree in every respect with that genus, except in the remarkable brevity of the antennæ.

**EUCHARIST, EUCHARISTIA,** the sacrament of the Supper, or a participation of the body and blood of Christ, under the species or figures of bread and wine. See **COMMUNION, SACRAMENT, SPECIES, TRANSUBSTANTIATION, and CONSUBSTANTIATION.**

The word in its original Greek, *Eucharistia*, literally imports *thanksgiving*, being formed of *eu*, *bene*, *well*, and *charis*, *gratia*, *thanks*.

**EUCHENDORF,** in *Geography*, a town of Lower Bavaria, on the Vils; 14 miles W. of Vilzhofen.

**EUCHERIUS,** in *Biography*, a bishop of Lyons in the fifth century, began his career in secular life, in the various offices of which he acquired wealth. He sustained the rank of senator, and having married, had several children, among whom were two sons, whom he lived to see advanced to the episcopal dignity. Wearied with the pursuits of the world,

he embraced a monastic life, which he quitted for the bishopric of Lyons in the year 434. He attended the deliberations of the first council of Orleans in the year 441, and was distinguished for his learning and sagacity. He was a popular preacher, upon those principles of grace which were vindicated by St. Augustine. He died about the year 454. Among the various pieces attributed to Eucherius, may be noted "Epistola de Laude Eremi, seu de Vita Solitaria," intended to extol the advantages of ascetic life, written, for the times, with uncommon beauty and purity of language: "Epistola Parænetica de contemptu Mundi, et Sæcularis Philosophiæ ad Valerianum Cognatum suum," which was published by Erasmus, with annotations, at Basil in the year 1520, and pronounced to be one of the most elegant pieces of antiquity. To these may be added two treatises intended to illustrate difficult passages of Scripture, of less value than those mentioned above. These, and some others attributed to Eucherius, were collected and published at Basil in 1531, at Rome in 1564, and are likewise to be found in the sixth volume of the "Bibliotheca Patrum." There was another Eucherius who was likewise a bishop of Lyons, and assisted at the second council of Orleans about the year 529. Moreri.

**EUCHITES,** or **ΕΥΧΙΤΑΙ,** in *Ecclesiastical History*, a sect of ancient heretics, who were first formed into a religious body towards the end of the fourth century, though their doctrine and discipline subsisted in Syria, Egypt, and other eastern countries before the birth of Christ; they were thus called because they prayed without ceasing, imagining that prayer alone was sufficient to save them.

Their great foundation was those words of St. Paul, Epist. i. to the Thessalonians, chap. v. ver. 17. *pray without ceasing.*

The word is formed of the Greek, *ευχη*, prayer, whence *ευχισταί*, the same with the Latin, *precatores*, prayers. They were also called *Enthusiasts* and *Mossalians*, a term of Hebrew origin, denoting the same as Euchites.

The Euchites were a sort of mystics who imagined, according to the oriental notion, that two souls resided in man, the one good and the other evil; and who were zealous in expelling the evil soul or dæmon, and hastening the return of the good spirit of God, by contemplation, prayer, and singing of hymns. They also embraced the opinions nearly resembling the Manichean doctrine, and which they derived from the tenets of the oriental philosophy. The same denomination was used in the twelfth century, to denote certain fanatics who infested the Greek and Eastern churches, and who were charged with believing a double Trinity, rejecting wedlock, abstaining from flesh, treating with contempt the sacraments of Baptism and the Lord's Supper, and the various branches of external worship, and placing the essence of religion solely in external prayer, and maintaining the efficacy of perpetual supplications to the Supreme Being for expelling an evil being or genius, which dwelt in the breast of every mortal. This sect is said to have been founded by a person called Lucope-trus, whose chief disciple was named Tychicus. By degrees it became a general and invidious appellation for persons of eminent piety and zeal for genuine Christianity, who opposed the vicious practices and insolent tyranny of the priesthood; much in the same manner as the Latins comprehended all the adversaries of the Roman pontiff under the general terms of *Waldenses* and *Albigenses*. Mosh. Eccl. Hist. Eng. edit. 8vo. vol. i. p. 350. and vol. ii. p. 441.

St. Cyril of Alexandria, in one of his letters, takes occasion to censure several monks in Egypt, who, under pretence of resigning themselves wholly to prayer, led a lazy,

lazy, scandalous life. A censure likewise applicable to monasteries in general.

**EUCHOLOGIUM**, *Ευχολογιον*, a Greek term, signifying, literally, *a discourse on prayer*.

The word is formed of *ευχης*, *prayer*, and *λογος*, *discourse*.

The Euchologium is properly the Greek ritual, wherein are prescribed the order and manner of every thing relating to the order and administration of their ceremonies, sacraments, ordinations, &c.

Fa. Goar has given us an edition of the Greek Euchologium in Greek and Latin, with notes, at Paris.

**EUCHROON**, in *Surgery*, a plaster mentioned by Scribonius Largus.

**EUCHYMIA**, from *eu*, *good*, and *χυμος*, *juice*, in *Medicine*, a good temper of the blood, or other juices and fluids in an animal body.

**EUCLABRIS**, in *Antiquity*, a table whereon the slaughtered victim was spread, in order to have its intestines carefully inspected. It was from this table that the vessels used in sacrifices were called *euclabria*.

**EUCLEASE**. The colour of this mineral is a very clear sea-green. It occurs only crystallized. Its primitive form is that of an oblique quadrilateral prism, but its summits are generally so complicated by truncatures and bevellings as to render a mere verbal description of it wholly unintelligible: in this state it resembles certain varieties of topaz, but may readily be distinguished by measuring the obtuse angles of the prism, which in this mineral are  $133^\circ$ , whereas in the topaz they are  $124^\circ$ ; its lamellæ also are not perpendicular to the axis of the prism. It has a brilliant vitreous lustre. Its fracture in the direction of its axis and parallel to the small diagonal of its base is perfectly lamellar; but when parallel to the large diagonal is very imperfectly so. Its cross fracture is somewhat conchoidal. It is transparent and has a double refraction. It is sufficiently hard to scratch quartz, but is remarkably brittle. Sp. gr. = 3.06.

When exposed to the blowpipe, it first loses its transparency, and then melts into a white enamel. It has been analysed by Vauquelin, with the following result:

Silex	-	-	-	-	35	to	36
Alumine	-	-	-	-	18	-	19
Glycine	-	-	-	-	14	-	15
Iron	-	-	-	-	2	-	3
<hr/>							
					69	-	73
Loss	-	-	-	-	31	-	27
<hr/>							
					100	-	100
<hr/>							

This mineral is so very rare that only a small portion could be afforded for analysis; of the loss, Vauquelin attributes the greatest part to water of crystallization, and the rest is probably alkali.

The euclase was found in Peru by Dombey, and all the specimens in the cabinets of Europe were brought over by this naturalist.

**EUCLEA**, in *Botany*, is derived by Professor Martyn from *εκλευα*, *glory*, or *celebrity*, which seems in no respect applicable to this plant. We would rather explain it by *eu*, *well*, and *ελευα*, *to shoot up*, because of the manifold coverings of the seeds, each of which is enclosed in an arillus, within the cell of a capsule, whose outside moreover is protected with a covering of pulp. To all this indeed L'Heritier first adverted, and not Linnæus nor Thunberg, one of whom probably invented the name. Linn. Suppl. 67. Thunb. Nov. Gen. 84. L'Herit. Sert. Angl. 31.

Schreb. 699, 700. Juss. 432. Class and order, *Dioclea Dodecandria*, or perhaps, as the Linnæan System now stands, *Polygamia Monoecia*. Nat. Ord. uncertain, Juss.

Gen. Ch. Cal. Perianth inferior, small, with five teeth, permanent. Cor. of one petal, larger than the calyx, in five deep, ovate, obtuse, equal, spreading segments. Stam. Filaments about fifteen, short, inserted into the receptacle; anthers erect, square, slightly downy, shorter than the corolla. Pysl. Germen superior, ovate, somewhat pyramidal; styles two, the length of the stamens; stigmas simple. Peric. Capsule with a pulpy coat, roundish, with three horns, three cells, and three valves. Seeds solitary, roundish, each enclosed in an arillus; one or two of them frequently proving abortive.

Ess. Ch. Calyx with five teeth. Corolla in five deep equal segments. Stamens 15. Styles two. Capsule superior, of three cells, pulpy-coated. Seeds solitary, enclosed in an arillus.

Obf. L'Heritier, from whom the above characters are taken, remarks that some flowers have an abortive germen, but he never saw any that were entirely female without stamens. Thunberg describes distinct male and female flowers, and asserts that the former are most frequently five-cleft, the latter four-cleft. Linnæus does not advert to any such difference.

Thunberg defines three species, all natives of the Cape of Good Hope, in his Prodrômus, p. 85.

1. *E. lancea*. "Leaves lanceolate, flat."
2. *E. racemosa*. "Leaves ovate, flat."—*E. racemosa*; Linn. Suppl. 428. L'Herit. Sert. Angl. 32. Ait. H. Kew. v. 3. 411. (*Padus foliis subrotundis, fructu racemoso*; Burm. Afric. 238. t. 84. f. 1; and *Euonymus foliis subrotundis integris, fructu corniculato*; *ibid.* 260. t. 97. f. 1. *E. africanus, foliis laurinis, fructu aculeato*; Breyn. Ic. 31. t. 22. f. 3.) A smooth branching shrub, with alternate, obovate, thick, somewhat revolute leaves, about an inch long, on short footstalks. Flowers eight or ten in each axillary drooping cluster, about as long as its corresponding leaf. Petals snow-white. Fruit red, the size of a pea.
3. *E. undulata*. "Leaves ovate, undulated."—Much like the last in general aspect. Its red fruit is eaten by the Hottentots, who call the plant *Guarri-boches*.

**EUCOLID**, in *Biography*, a native of Megara, and founder of the Megaric or Eristic sect, was distinguished by his subtle genius, and early application to the study of philosophy. Having acquired some knowledge of the art of disputation from the writings of Parmenides, he was induced by the fame of Socrates to remove from Megara to Athens, where he became the auditor and disciple of this eminent philosopher. Notwithstanding the terror of the decree which enacted, that any inhabitant of Megara who should be seen at Athens should forfeit his life, he frequently came to Athens by night, from the distance of about 20 miles, concealed in a long female cloak and veil, to visit his master. He also frequently engaged in the business and disputes of the civil courts, by which proceeding he offended Socrates, who despised forensic contests; and this circumstance seems to have occasioned a separation between them. Afterwards he put himself at the head of a school in Megara, where his chief employment was to teach the art of disputation. Although he was much addicted to vehement debates, he possessed so great a command of temper, that in a quarrel with his brother, who said to him, "Let me perish if I be not revenged upon you," Euclid replied, "And let me perish, if I do not subdue your resentment."

ferment by forbearance, and make you love me as much as ever."

Averse from the analogical method of reasoning, Euclid was of opinion that legitimate argumentation consists in deducing fair conclusions from acknowledged premises. He held, that there is one supreme good, which is called by the different names of Intelligence, Providence, God; and that evil, considered as an opposite principle to the sovereign good, has no physical existence. The supreme good he defined to be that which is always the same. Good he therefore considered abstractedly, as residing in the Deity, and he seems to have maintained, that all things which exist are good by their participation of the first good, and that in the nature of things there is no real evil. When Euclid was asked his opinion concerning the gods, he replied, "I know nothing more of them than this; that they hate inquisitive persons." Brucker's Hist. Phil. by Enf. v. i.

EUCLID, known to every well educated youth by his "Elements," was, according to the testimony of Pappus and Proclus, a native of Alexandria, in Egypt, where he flourished and taught the mathematics in the reign of Ptolemy Lagus, about 300 years before Christ. His was the first mathematical school in that far famed city, where, till its conquest by the Saracens, most of the eminent mathematicians were either born, or studied. To Euclid, and to those immediately educated by him, the world has been indebted for Eratosthenes, Archimedes, Apollonius, Ptolemy, &c. "The Elements," to which we have already referred, are not to be wholly attributed to Euclid, many of the invaluable truths and demonstrations contained therein were discovered and invented by Thales, Pythagoras, Eudoxus, and others; but Euclid was the first who reduced them to regular order, and who probably interwove many theorems of his own, to render the whole a complete and connected system of geometry. "The Elements" consist of fifteen books, but the last two are suspected to have been written 200 years after Euclid's death, by Hypsicles of Alexandria. The best edition published in this country is that printed at Oxford, in folio, in 1703; but the most common edition in our schools is that by the late learned Dr. Simson. Euclid is said to have been a person of agreeable and pleasing manners, and admitted to habits of friendship and familiarity with king Ptolemy, who once demanded of the mathematician if he could not direct him to some shorter and easier way of acquiring a knowledge of geometrical truths, than that which he had exhibited in his "Elements," to which Euclid replied, that "there was no royal road to geometry."

Euclid, as a writer on music, has ever been held in the highest estimation by all men of science who have treated of harmonics, or the philosophy of sound. As Pythagoras was allowed by the Greeks to have been the first who found out musical ratios, by the division of a monochord, or single string, a discovery which tradition only had preserved, Euclid was the first who wrote upon the subject, and reduced these divisions to mathematical demonstration.

His "Elements" were first published at Basil, in Switzerland, 1533, by Simon Gryneus, from two MSS. the one found at Venice, and the other at Paris. His "Introduction to Harmonics," (*Εισαγωγή ἁρμονικῆς*), which in some MSS. was attributed to Cleonidas, is in the Vatican copy given to Pappus; Meibomius, however, accounts for this, by supposing those copies to have been only two different MS. editions of Euclid's work, which had been revised, corrected, and restored from the corruptions incident to frequent transcription by Cleonidas and Pappus, whose names were, on that account, prefixed. It first appeared in print

with a Latin version, in 1498, at Venice, under the title of "Cleonidæ Harmonicum Introductorium:" who Cleonidas was, neither the editor, George Valla, nor any one else pretends to know. It was John Pena, a mathematician in the service of the king of France, who first published this work at Paris, under the name of Euclid, in 1557. After this, it went through several editions with his other works.

His "Section of the Canon," (*Κατάτομὴ κανόνος*;) follows his "Introduction;" it went through the same hands and the same editions, and is mentioned by Porphyry, in his Commentary on Ptolemy, as the work of Euclid. This tract chiefly contains short and clear definitions of the several parts of Greek music, in which it is easy to see that mere melody was concerned; as he begins by telling us, that the science of harmonics considers the nature and use of melody, and consists of seven parts: sounds, intervals, genera, systems, keys, mutations, and melopœia; all which have been severally considered in the dissertation.

Of all the writings upon ancient music, that are come down to us, this seems to be the most correct and compressed: the rest are generally loose and diffused; the authors either twisting and distorting every thing to a favourite system, or filling their books with metaphysical jargon, with Pythagoric dreams, and Platonic fancies, wholly foreign to music. But Euclid, in this little treatise, is like himself, close and clear; yet so mathematically short and dry, that he bestows not a syllable more upon the subject than is absolutely necessary.

His object seems to have been the compressing into a scientific and elementary abridgment, the more diffused and speculative treatises of Aristoxenus. He was the D'Alembert of that author, explaining his principles, and, at the same time, seeing and demonstrating his errors. The musical writings of Rameau were diffused, obscure, and indigested; but M. D'Alembert, extracting the essence of his confused ideas, methodized his system of a *fundamental base*, and compressed, into the compass of a pamphlet, the substance of many volumes. See *Elemens de Musique, suivans les Principes de Rameau*.

According to Dr. Wallis, (*Phil. Transf. No. 242*, and *Lowthorp's Abridg. v. i.*) Euclid was the first who demonstrated that an octave is somewhat less than six whole tones; and this he does in the 14th theorem of his "Section of the Canon." In the 15th theorem he demonstrates that a fourth is less than two tones and a half, and a fifth less than three and a half; but though this proves the necessity of a temperament upon fixed instruments, where one sound answers several purposes, yet he gives no rules for one, which seems to furnish a proof that such instruments were at least not generally known or used by the ancients.

What Aristoxenus called a *half-tone*, Euclid demonstrated to be a smaller interval, in the proportion of 256 to 243. This he denominated a *limma*, or *remnant*; because giving to the fourth, the extremes of which were called *soni stabiles*, and were regarded as fixed and unalterable, the exact proportion of 4 to 3, and, taking from it two major tones  $\frac{3}{2} \times \frac{3}{2}$ , the limma was all that remained to complete the diatessaron. This division of the diatonic genus being thus, for the first time, established upon mathematical demonstration, continued in favour, says Dr. Wallis, for many ages. But this is further explained in other articles.

EUCOMIS, in *Botany*, from *ευχομῆς*, *having beautiful hair*, alluding to the leafy tuft of barren bractæas, which crowns the spike of flowers. See *COMA*.—L'Herit. Sert. Angl. 17. Ait. Hort. Kew. v. 1. 432. Schreb. 798. Willd. Sp. Pl. v. 2. 92. Mart. Mill. Dict. v. 2. (*Basilæa*; Lamarck Encycl.

Encycl. v. 1. 382. t. 239. Juss. 52. Venten. v. 2. 163. Fritillaria; Linn. Gen. 164.) Class and order, *Hexandria Monogynia*. Nat. Ord. *Coronaria*, Linn. *Alphodelis*, Juss.

Gen. Ch. *Cal.* none. *Cor.* of one petal, inferior, bell-shaped, regular, permanent, in six deep, equal, oblong, obtuse, spreading segments. *Stam.* Filaments six, shorter than the corolla, awl-shaped, dilated at the base and united by that part into a concave nectary, attached to the bottom of the corolla; anthers oval. *Pist.* Germen superior, ovate, with three furrows; style awl-shaped; stigma simple. *Peric.* Capsule ovate, three-lobed, of three cells. *Seeds* numerous, small, ovate.

Eff. Ch. Calyx none. Corolla inferior, in six deep, spreading, permanent, equal segments. Filaments united at their base into a concave nectary, attached to the corolla.

1. *E. nana*. Ait. Hort. Kew. v. 1. 432. Jacq. Hort. Schoenbr. v. 1. 47. t. 92. (*Fritillaria nana*; Linn. Mant. 223.) Stalk club-shaped. Leaves numerous, broad-lanceolate, crenate. Barren bractees elliptical.—Native of the Cape of Good Hope, as are all the known species. *Bulb* ovate, rather large. *Leaves* radical, about eight, pale-green, spreading, recurved, obovato-lanceolate, somewhat acute. *Stalk* solitary, a span high, green, swelling considerably upwards, bearing a short spike of green drooping flowers, surmounted with a tuft, about as long as the spike, consisting of elongated, elliptical, barren bractees. It is kept in the greenhouse, and flowers in the spring, but is scarcely cultivated except for the sake of curiosity.

2. *E. bifolia*. Jacq. Ic. Rar. v. 2. t. 449. Coll. v. 4. 215. Curt. Mag. t. 840. (*Melanthium maffoniaefolium*; Andr. Repof. t. 368.)—Stalk club-shaped. Leaves two, elliptical, depressed. Bractees all longer than the flowers, pointed, recurved.—The leaves are ribbed, entire, very broad. *Stalk* very short, green. Barren and fertile bractees uniform, and all longer than the flowers, which are sessile and erect.

3. *E. purpurea*. (*E. purpureocaulis*; Andr. Repof. t. 369.) Stalk club-shaped. Leaves numerous, obovate, obtuse, depressed. Fertile bractees shorter than the flowers; barren ones linear-lanceolate.—Drawn by Mr. Andrews in the garden of G. Hibbert, esquire.—The broad, depressed, numerous leaves; thick, violet stalk; and numerous, narrow, purple-edged leaves of the crown, readily distinguish this species.

4. *E. regia*. Ait. H. Kew. v. 1. 433. (*Fritillaria regia*; Linn. Sp. Pl. 435. *Corona regalis*, *lilii folio crenato*; Dill. Elth. t. 92, 93.)—Stalk cylindrical. Leaves tongue-shaped, crenate, depressed. Barren bractees elliptical.—This most resembles the first species in size, habit, colour, and the crenate edges of its leaves; but differs in its longer cylindrical stalk. It has been much longer cultivated than any other of the genus.

5. *E. undulata*. Ait. ibid. Curt. Mag. t. 1083. (*E. regia*; Redout. Liliac. v. 3. t. 175. *Basilæa*; Lamarck f. 1.)—Stalk cylindrical. Leaves ovate-oblong, undulated, spreading. Barren bractees almost as long as the spike.—Introduced in 1760 by Mr. Miller, who, from its blossoming in autumn, which is not invariable, named it *Fritillaria autumnalis*. *Stalk* taller than in the last. *Leaves* narrower and longer. Mr. Gawler observes that their undulations disappear as they decay.

6. *E. punctata*. L'Herit. Sert. Angl. t. 18. Curt. Mag. t. 913. (*Basilæa*; Lamarck f. 2.)—Stalk cylindrical. Leaves lanceolate, channelled, spreading. Spikes many times longer than the barren bractees.—The long narrow leaves, stalk elegantly speckled with violet, and especially

the great extent of the spike, which is about a foot in length, render this species very distinct. The corolla is of a very pale green. *Germen* violet. The bases of the leaves are externally spotted like the stalk. It flowers in June or July, and is easy of cultivation.

EUCRASY, of *eu*, well, and *κρᾶσις*, temperature, an agreeable, well-proportioned mixture of qualities, whereby a body is said to be in good order, and disposed for a good state of health.

EUCRYPHIA, in *Botany*, from *eu*, well, and *κρυπτος*, covered, because the flower-buds are concealed by a peculiar covering. Cavan. Ic. v. 4. 48. Class and order, *Polyandria Polygynia*. Nat. Ord. *Tiliaceæ*, Juss.

Gen. Ch. *Cal.* Perianth inferior, of five minute, ovate, equal, permanent leaves. *Cor.* Petals five, large, obovate, equal, spreading; covered before expansion with a deciduous veil, separating from the base into four segments. *Stam.* Filaments inserted into the receptacle, numerous, awl-shaped, shorter than the petals; anthers roundish, of two cells. *Pist.* Germen superior, ovate, striated; styles about 12, shorter than the stamens; stigmas simple. *Peric.* Capsule ovate, with a woody furrowed bark, bursting at the top and bottom into as many cells as there are styles, each remaining attached by two fibres to the receptacle. *Seeds* several, obovate, imbricated, each terminated by a small membranous wing.

Eff. Ch. Calyx of five small leaves. Petals five, covered before expansion with a deciduous veil. Capsule of many cells, separating at top and bottom. *Seeds* winged, imbricated.

1. *E. cordifolia*. Cavan. Ic. v. 4. 49. t. 372.—A fine tree gathered in Chili, by Louis Née, from whose herbarium Cavanilles described it. *Wood* red. *Branches* downy when young. *Leaves* opposite, on short stalks, ovate, obtuse, undulated and bluntly crenate, veiny, coriaceous; heart-shaped at the base; smooth above; downy and white beneath; scarcely two inches long. *Stipulas* none. *Flowers* axillary, solitary, each on a stalk about an inch long, with a few scales at its base. *Petals* white, turning red in drying. *Veil* of the flower externally downy.—It is commonly called in the country *Roble di Chile*, or Chili Oak.

EUDEMIA, in *Ancient Geography*, a small island of the Ægean sea, placed by Pliny in the Thermaic gulf.

EUDÆMON, JOHN ANDREW, in *Biography*, a learned Jesuit, was a native of Candia, and went to Rome in pursuit of knowledge, where he entered himself a member of the society of Jesus. He was afterwards professor of philosophy, and then of theology in the university of Padua. He was honoured with the esteem and friendship of Pope Urban VIII. who appointed him the chaplain to his own nephew cardinal Barberini, when he was sent papal legate into France. He died at Rome in 1625, leaving behind him in various publications many testimonials to his talents and learning. He was suspected to be the author of a work entitled "Admonitio ad Regem Ludovicum XIII." which attacked the authority of the kings of France, in matters of an ecclesiastical nature. This treatise brought the society, of which Eudæmon was a member, into great and general disrepute; it was likewise censured by the faculty of the Sorbonne, and the assembly of the clergy at Paris, and condemned by the parliament. Moreri.

EUDEMUS, in *Biography*, a name, it would appear, common to several physicians in different ages, of whom little is known with any degree of certainty or precision. One Eudemus is mentioned by Galen as contemporary with Herophilus, in the 37th age, and is compared with the latter in respect to his anatomical skill, especially relative to

the nerves. Another Eudemus is said to have suffered death for his crimes, in the year 31 of the Christian era. And others of the same name, as Eudemus the vendor of antidotes, Eudemus of Chio, are occasionally mentioned. See Eloy. Dict. Hist.—Le Clerc Hist. de la Médecine.

Eudemus of Rhodes was a pupil of Aristotle. The Ethics of Aristotle are inscribed to him, and some suppose them to have been written by him.

EUDES, duke of Aquitain, succeeded to his dukedom towards the close of the seventh century. When Pepin Herital laid claim to the royal authority in France, Eudes declared himself independent, and seized upon the remainder of Aquitain, and in a short time by force of arms made himself master of all the country lying between the Loire, the Ocean, the Pyrenées, Septimania, and the Rhone. In 721 he defeated Zama, lieutenant of the Saracen caliph, who had invaded Gaul, under the walls of Toulouse, but in a few years afterwards he found it necessary to make an alliance with Munuza, another Saracen general, to whom he gave his daughter in marriage. After this his country was completely over-run by the Saracens, over whom, by the aid of Charles Martel, he obtained, in 732, a complete victory, which delivered France from the Mahometan yoke. Eudes died in 735, leaving behind him three sons by his wife Valtrude, who was the near relation of Pepin. Moreri. Univer. Hist.

EUDES, JOHN, born at Rye in Lower Normandy, in the year 1601, was brother of the celebrated historian Mezerai, and received his education at Caen, under the care of the Jesuits, where he was afterwards entrusted with the superiority of the house belonging to the congregation. In 1643 he quitted the duties of this institution, and undertook the establishment of another, of which he became the first superior as well as founder. This was denominated "The congregation of Jesus and Mary," and the principal object of it was to provide a seminary for the instruction of young persons in piety and sacred knowledge, and to form a body of religionists, influenced by greater fervour and exaltation in their devotional feelings, than was encouraged by the regulations of the society of which he had been a member. He died in 1680, at the age of seventy-nine. He is described as having been an excellent and well-meaning man, but mystical and highly enthusiastic. As a preacher and instructor of youth, he was very popular; but his writings evince little knowledge and less judgment, though they exhibit a devotional spirit, tinged with large portions of superstitious credulity. The most remarkable of his pieces are (1) A treatise "On the Devotion and Office of the Heart of a Virgin; (2) "Man's contract with God;" and, (3) some particulars concerning a peasant in Normandy, whom he regarded as under divine inspiration, entitled "The life of Mary of the Vallies." Moreri.

EUDIOMETRY. This term is applied to those processes which have been employed to ascertain the purity, or, in other words, the degree of oxygenation of any gaseous mixture, and especially of atmospherical air.

A considerable variety of methods have been used by chemists, all of which, though essentially different, agree in acting upon the oxygenous portion alone, the azot being in all cases left as the unchanged residue. The following are the several methods employed.

*Of nitrous gas as an eudiometer.*—This was the first eudiometer used by Dr. Priestley in his original experiments on air, which immediately followed the discovery of oxygen by this illustrious philosopher. If nitrous gas be mixed with oxygen gas, in a glass jar over water, in the proportions in which they saturate each other, to form nitric acid, the

gases will totally disappear, a ruddy fume is seen at the moment of mixture, and the water will rise to the top of the jar, leaving unabsorbed only the unavoidable impurities of the gases. If, on the other hand, nitrous gas be mixed with atmospherical air, or any other admixture of oxygen and azot, the former alone of the two will be condensed by and with the nitrous gas, and the azot will remain unaltered. Hence by measuring the respective quantities of the gases employed, and the quantity absorbed, the purity of the atmospherical air may be ascertained, (supposing it known by previous experiment what are the exact proportions in which nitrous gas and oxygen saturate each other, and become totally absorbable by water.) Thus, for example, if 100 measures of nitrous gas be added to the same quantity of common air; and the two completely mixed, the bulk after such mixture will not be 200 measures, but only about 108, and consequently 92 measures will have been absorbed; which last, therefore, consist of all the oxygen of the air, with so much of the nitrous gas as has been employed to saturate it. This result Dr. Priestley was in habit of denoting, for brevity sake, by the expression that the air was of the purity of 108, by which he always meant that when 100 of nitrous gas, and 100 of the air to be examined were mixed, the residue after the mutual action of the airs was over, was of the number specified. The quantity of the two airs absorbed being known, the portion which is estimated to belong to the oxygen must therefore depend on the proportion in which nitrous and oxygen gases saturate each other, which requires another elementary experiment. Thus in the instance before us, if three parts of nitrous gas saturate one part of oxygen, the 92 parts which have disappeared are composed of 69 of the former gas, and 23 of the latter, and hence the composition of the 100 parts of atmospherical air examined, will be 23 of oxygen, and the remainder unabsorbed residue chiefly azotic.

A number of valuable experiments by Fontana, Ingenhousz, and especially by Mr. Cavendish, made on this subject, have shewn that different portions of the very same mixture of nitrous gas and oxygen will experience a prodigious difference of absorption according to the width of the tube in which they are mixed, the order of mixture, the time of standing together, the degree of agitation used, and other manipulations. Thus Mr. Cavendish observed, that if one measure of nitrous gas and as much common air be rapidly mixed, and immediately shaken, the absorption will be nearly half the entire contents, but if the airs are suffered to remain in contact for about a fourth of a minute before they are shaken, the absorption will be no more than about .8. The nature of the water also in which the experiment is made is found very materially to influence the result. By attending to every circumstance of the kind, Mr. Cavendish, with that admirable accuracy which distinguishes all the researches of this eminent philosopher, was enabled to obtain very satisfactory results as to the uniform nature of atmospherical air.

Still, however, the difficulties of employing this mode of analysis with sufficient precision in all admixtures of oxygen and azot have been found so great, and the apparent anomalies so numerous, that it has been long nearly abandoned by chemists, till of late the subject has been revived by Mr. Dalton, who has added some important observations, which require some notice in this place. (See the Manchester Transactions. New series.)

Mr. Dalton gives the following experiments:

If 100 measures of common air be thrown up to 36 measures of nitrous gas in a tube only 3-10ths of an inch wide,

## EUDIOMETRY.

wide, and 5 inches long, and no agitation be used, in a few minutes the whole will be reduced to 79 or 80 measures, and exhibit no signs of either oxygen or nitrous gas, but will consist entirely of azot.

If on the other hand 100 measures of common air be thrown up to 72 of nitrous gas, in a wide vessel over water, such as to form a thin stratum of air, and an immediate agitation be used, both the oxygen and the nitrous gas will, as before, totally disappear, and the residue, as before, will also be 79 or 80 measures of azot.

If in the last experiment less than 72 measures of nitrous gas be used, there will be a residuum containing some oxygen; if more, the residue will contain nitrous gas.

From these elementary experiments Mr. Dalton infers that the oxygen, contained in 100 parts of common air, may unite totally either with 36 parts of nitrous gas, or with 72, double that quantity, but with no intermediate portion. To insure the former effect, the gases must be mixed in a narrow vessel without agitation; to insure the latter the vessel must be large, and the points of contact between the ingredients must be increased by agitation. But in the ordinary circumstances of the experiment, Mr. D. supposes that both these effects partially take place, so that one part of the oxygen unites with the nitrous gas in the smaller proportion, and another in the larger; and hence he accounts in a very ingenious and satisfactory manner for the greater part of the apparent anomalies which have been observed in the employment of nitrous gas in eudiometry. Therefore, he observes, to use nitrous gas for the purpose of eudiometry, we must attempt to form one or other of these combinations wholly, and he prefers that with the smallest proportion of nitrous gas, in the following way:

Take a narrow tube of the dimensions above given, add 100 parts of common air to about 36 of nitrous gas, and when the diminution is complete, without agitation, transfer the residue to another tube and measure it; then  $7\frac{1}{5}$ ths of the loss will be due to the oxygen present.

But a stronger objection arises against the employment of nitrous gas in its aeriform state, owing to the difficulty of obtaining this gas of uniform purity. From a very elaborate series of experiments on this subject, undertaken by Humboldt and Vauquelin, (*Ann. Chem.* tom. 28.) it appears that when nitric acid of any strength is poured upon copper wire (which is the usual mode of obtaining nitrous gas,) an effervescence more or less vehement takes place, and a gas is disengaged, consisting of nitrous gas, but always mixed with more or less of azotic gas, and sometimes nitrous oxyd, and it is this varying portion of azot which constitutes the chief difficulty and trouble in the employment of nitrous gas in eudiometry. The quantity of azot is found to depend largely on the strength of the acid being from about one-tenth or less to nearly half the entire gas. According to Humboldt, the degree of strength of acid which produces the purest nitrous gas, is that in which the specific gravity is about 1.15 to 1.17, or from 17 to 21 of Beaume's areometer. Mr. Dalton finds that nitric acid diluted with an equal bulk of water poured on copper and mercury, without any artificial heat being used, gives a nitrous gas nearly pure, or with only from two to three per cent. of azot.

The proportion of azotic impurity in any mixture of this with nitrous gas, is most conveniently ascertained by agitating the gas with a solution of green sulphat of iron, which absorbs the nitrous gas without materially affecting the other. This experiment was first made by Dr. Priestley, who found that the solution of iron acquired thereby a reddish or olive brown colour, and a very acid styptic taste.

Other chemists have also found a certain quantity of ammonia in the solution.

To obviate the objections brought against the use of nitrous gas, in the gaseous form, as an eudiometer, Mr. Davy has ingeniously applied to this purpose the solution of sulphat or muriat of iron, saturated with nitrous gas as above-mentioned; and this, with a few precautions, is found to answer with great precision, and to be applicable with little trouble to all cases of the analysis of gases where oxygen is one of the substances sought for. The mode of use in ordinary cases is as simple as possible. The gas is put into a graduated eudiometer tube, some of the solution is poured in, and by very gentle agitation for about a minute, the whole of the oxygen is absorbed. The chief precautions required are, not to use the same solution twice, to keep it in a well-stopped bottle, and particularly to remove it from the gas under analysis as soon as the utmost degree of absorption is produced, as after this time a small increase of bulk is again observable in the residue, owing probably to some evolution of gas from the solution. It is also found that if the solution be very highly impregnated with the nitrous gas, and much hasty agitation be used, a little of the nitrous gas escapes in the gaseous form into the eudiometer tube, which may be removed by the application of a little sulphat or muriat of iron. One cubic inch of the impregnated solution of moderate strength will absorb about five or six cubic inches of oxygen gas.

*Of the sulphurets as eudiometers.*—The eudiometer first employed by the illustrious Scheele, in his original experiments on the constitution of the atmosphere, so early as the year 1779, was a mixture of iron filings and flowers of sulphur, moistened with a little water. By confining a cup of this mixture under a jar of common air over water, this excellent chemist observed an absorption soon to begin, the water gradually rising in the jar for about eight hours, after which no further diminution took place, and the residuary gas consists chiefly of azot.

This valuable elementary experiment has been employed in eudiometry with great advantage, but modified considerably, and a few precautions must be taken to avoid inaccuracies. In the first place it is to be observed that this mixture of iron filings and sulphur is slow in its operation, and moreover, a quantity of hydrogen gas is given out towards the end, which mixes with the residuary azotic gas. To lessen the duration of the experiment the liquid alkaline or earthy sulphurets have been substituted to the mixture of iron filings and sulphur, with great advantage. When atmospherical air, confined in a tube, is shaken for a few minutes with a little of the liquid sulphuret of lime, potash, or soda, the whole of the oxygen is absorbed in a few minutes.

Guyton has proposed to hasten the absorption by heating the solution, but it has been found that in this case there is some danger of expelling from it a portion of sulphurated hydrogen gas, which would impair the accuracy of the experiment.

A more important source of error has been mentioned by Marti, (*Journal de Physique*, tom. 52.) which must be avoided. It appears from his experiments that liquid sulphuret of lime, (and probably the other liquid sulphurets,) when recently made, is capable of absorbing a portion of azot as well as oxygen, which, though small, is sufficient to affect materially the result of a delicate experiment. Marti found that when one measure of common air was shaken with 20 measures of the liquid sulphuret of lime, the entire absorption amounted to as much as 26 per cent. of the air. But of these it is known that only about 21 can

## EUDIOMETRY.

be oxygen, and consequently about 5 of azot must have been absorbed. The experiment being repeated with the same solution, only 21 per cent. were now absorbed, so that the solution had been saturated with azot by the previous experiment. The same solution was then shaken with pure azot, but no absorption took place, which confirmed the fact of the previous saturation of the sulphuret with azot. On the other hand, when a perfectly fresh solution was used, which immediately after being prepared, had been allowed to cool in a well-closed bottle, and only a twentieth of its bulk of common air was confined with it, the latter in a few minutes had diminished full one-half.

It is easy to avoid errors from this circumstance. All that is necessary is, previously to using the liquid sulphuret as an eudiometer, to shake it for a few minutes in a bottle of common air, and it is never necessary to use more than about two measures of the sulphuret to one of common air. With these precautions, the sulphuret proves a very useful and accurate eudiometer.

*Of hydrogen gas as an eudiometer.*—This ingenious method was proposed and employed with great success by the celebrated Volta. It consists in mixing known proportions of pure hydrogen gas with the air to be examined in a very strong glass tube, through which a metallic communication is made, and detonating the contents by the electric spark. After the shock, a sudden diminution takes place, owing to the production of water by the detonation of the hydrogen with the oxygen contained in the air examined. The exact saturating proportion between the two gases has been variously given, but an excess of hydrogen should be used. One hundred parts of oxygen require at the highest estimation somewhat less than 200 of hydrogen for saturation; so that when equal bulks of hydrogen and *atmospheric air* are used, there is an abundant allowance of hydrogen. Mr. Dalton finds 60 of the latter sufficient for 100 of common air, and the diminution is very uniformly 60 parts with the above proportions; and hence, if common air contains 21 per cent. of oxygen, the saturating proportions of oxygen and hydrogen are 21 of the former to 39 of the latter.

The chief objection to the universal use of Volta's eudiometer is, that it requires an apparatus to give the electric spark, which cannot be always procured; and in all experiments of this kind it is particularly desirable to employ one uniform mode of experimenting where general results are to be established.

*Of phosphorus as an eudiometer.*—Phosphorus has two distinct modes of combustion in common air, according to the temperature to which it is raised. One of these is rapid, and attended with the evolution of a prodigious quantity of light and heat, and it occurs when phosphorus is heated a little above its melting point, or in common language is set fire to. The other takes place in a temperature not exceeding from 90° to 100° at the utmost, and is that in which the phosphorus emits copious fumes, white in the day-time but highly luminous in the dark, and without any sensible emission of heat. In either case the phosphorus is consumed, or oxygenated; but it is the slow combustion without sensible heat that is alone employed in eudiometry. The whole apparatus required for the purpose is simple and convenient of application. Nothing more is necessary than to fix a stick of phosphorus in a portion of glass tube run through a cork, which loosely fits the open end of the small jar which is to contain the air to be analyzed, and confine it by water. If the temperature is very cold, the process may be assisted by the warmth of the hand. The phosphorus is immediately surrounded by the white luminous fume, which slowly falls down to the surface of the water, during which

time the oxygen of the air is gradually abstracted by the vaporized phosphorus, and in consequence the bulk of the contained air is diminished. The absorption of oxygen is complete when the contained gas is no longer luminous, which, in a small jar with a stick of phosphorus that traverses nearly its whole length, requires about half an hour at the heat of from 70° to 80°. The process succeeds equally well at a lower temperature, though a longer time is required. The heat cannot be safely raised more than about 85° or 90°, without danger of kindling the phosphorus, which may be avoided by observing that it melts and becomes glossy just before it catches fire.

The exact operation of the slow combustion of phosphorus used in this experiment has been very happily explained by Goettling and Berthollet. When phosphorus is exposed to air at any temperature below that of rapid combustion, the first effect seems to be a solution of the surface in the azot of the surrounding air, and this phosphorized azot instantly unites with the oxygen, becomes thereby luminous, and phosphorus acid absorbable by water is generated. Hence it is (strictly speaking) only that portion of phosphorus which becomes dissolved in the azot which is the eudiometrical substance; and in confirmation of this it may be added that phosphorus inclosed in pure oxygen gas is not in any degree luminous, but remains perfectly inactive till the heat is raised to the point of strong combustion. On the other hand, if the purest possible azot is passed into a jar full of water, and containing a stick of phosphorus, the gas only becomes luminous for a very short time, after which this appearance ceases, but the azot continues to saturate itself with phosphorus. If now a bubble of common air or oxygen is let up into this phosphorized azot, the luminous appearance immediately returns, and continues so till all the oxygen is exhausted. Phosphorus, therefore, furnishes also an useful test of the purity of azot, by not becoming luminous in it, but by enabling it to become luminous as soon as a particle of oxygen is added.

One circumstance of importance should be added, which is, that azotic gas in saturating itself with phosphorus is found to expand about 1-40th of its bulk, which accounts for the apparent difference in the composition of common air as determined by phosphorus or by other eudiometrical substances. After all absorption has ceased, when phosphorus is used, the apparent loss is not more than from 20 to 21 per cent. of the atmospheric air employed, whereas with all the other eudiometrical processes the loss is from 21 to 22 per cent., but this difference may be chiefly accounted for by the expansion of the residual azot from its saturation with phosphorus. It is therefore more accurate to diminish the bulk of the residuum by 1-40th, and this diminution must be thrown into the side of the oxygen absorbed. In analyzing an air much more oxygenous than the atmosphere, in proportion as the azotic ingredient diminishes, the operation of the phosphorus in removing the oxygen becomes less rapid and powerful, and hence either a dilution with pure azot is adviseable, or some other eudiometrical test should be preferred.

The general results of all the operations of atmospheric air have established it as an incontestible truth, that scarcely any difference exists in the proportion of oxygen, whatever be the height, season of the year, climate, and temperature at which the experiment is made, and even where the greatest changes would be expected from vitiation of air by the respiration of crowded assemblies of people, and the like, the loss of oxygen is much less than would have been generally expected. Hence the utility of eudiometry as a measure of the purity of the atmosphere has much diminished since this

fact

fact has been established, but the numerous and acute researches to which the subject has led, have been of high importance to this difficult part of chemical research.

Several kinds of apparatus are used in eudiometrical experiments, some of which may be here described.

*Dr. Hope's eudiometer* is the following. (*Plate X. Chemistry, fig. 1.*) It consists of two parts, the lower of which is a short thick bottle, with an upper and a side opening, the latter closed by a glass stopper, and the other receiving a graduated tube closed at the top, and accurately fitted by grinding. To use it, take off the tube, and fill it quite full of the gas to be examined, and also fill the bottle with liquid sulphuret of lime, and, without shaking, sink it in water, and then immerse the open end of the graduated tube in the same water, and slide it upon the bottle and thrust it in. Then take out the bottle and tube, and shake them, to bring the sulphuret thoroughly in contact with the contained gas, and immerse the bottle from time to time in water, opening the side stopper to allow the water to rush in, and supply the vacuum made by the absorption of oxygen. This will indeed somewhat dilute the eudiometrical liquor, but not so much as to prevent it from acting. When all absorption is over, the quantity of residual gas is found by inspection of the scale of the graduated jar.

The apparatus for detonating oxygen and hydrogen, which forms Volta's eudiometer, consists of a very thick graduated glass tube, open at bottom, and towards the top are two sealed holes, admitting the wires by which the electric spark is taken. A very useful improvement in this apparatus has been introduced by Mr. Pepys, to prevent the violence of the shock, either from breaking the glass (with moderate quantities) or from throwing out any of the mercury when confined by this fluid. In this improved apparatus, the thick graduated jar is fixed to a heavy iron stand, which has a strong spring near the foot, that draws out in the manner of the steel-yard, when the concussion is given, and thus takes off the recoil. *Fig. 2.*

An improved and very useful apparatus for nice eudiometrical experiments, is given by Mr. Pepys in the *Phil. Trans.* for 1807, to which we shall refer our readers for a full description. It consists of a graduated tube, an elastic gum-bottle, furnished with a perforated glass stopper, closely fitting to the end of the tube, and another very small tube with a surrounding jar for the purpose of measuring quantities less than the smallest subdivisions of the larger graduated tube. The eudiometrical liquor is put into the elastic gum-bottle, and by pressure is injected strongly up into the larger tube, by which means the action is facilitated, and none of the liquor is spilled or wasted.

**EUDOCIA**, in *Biography*, a Roman empress, wife of Theodosius the younger, was daughter of Leontius, an Athenian philosopher. She was educated in the sciences and religion of ancient Greece, and so great were her mental acquirements and personal beauty, that Leontius divided his property between his sons, conceiving she could stand in need of nothing to recommend her to a proper husband. About the year 421 she was married to Theodosius, when she renounced the errors of paganism, and received the baptismal name of Eudocia, having previously been called Athenais. She was reconciled to her brothers; and, having invited them to court, conferred upon them offices of rank and power. Upon the throne, as in a more humble station, she cultivated letters, and employed her talents in the service of the religion to which she was a convert. She put into verse several of the books of the Old Testament, and wrote paraphrases on some of the Jewish prophets. She lived for a considerable time in harmony with her consort;

and after the marriage of her daughter to the emperor Valentinian III. she was permitted to pay her vows in a splendid pilgrimage to Jerusalem; and at Antioch she pronounced an oration to the senate from a throne of gold. After her return, suspicions were excited of her fidelity in the breast of her husband by his sister Pulcheria, who had been the means of bringing them together by marriage. The object of these suspicions was Paulinus, a handsome and accomplished man, who held high offices at court, and who was put to death on the occasion. Eudocia was reduced to a private condition, and allowed to seek a retreat in the Holy Land, where she had formerly obtained a high degree of credit by the magnificence of her presents. Here she devoted herself to religious and devotional studies, and died in 460 at the age of 67. In her last illness, she asserted in the most solemn manner her innocence of the crime for which she had been dethroned and suffered banishment. *Moreri. Gibbon's Hist.*

**EUDOCIAS**, in *Ancient Geography*, an episcopal town of Asia, in Pamphylia.—Also, an episcopal town of Asia, in the second Galatia.

**EUDON**, a river of Asia, in Caria.

**EUDOXIANS**, a party or sect of heretics in the fourth century, so denominated from their leader Eudoxius, a native of Arabissus in Armenia Minor, and patriarch of Antioch, to which he was advanced in 356, and Constantinople, to which he was promoted in 359, and which he retained till his death, in 370. He was a great defender of the Arian doctrine, though represented as somewhat fluctuating and unsteady in his principles. He is charged with being a bitter persecutor of the Catholics. Of his works, no remains are extant, except some fragments of a treatise "De Incarnatione Dei verbi;" to which Cave (*Hist. Lit.*) has referred.

The Eudoxians adhered to the errors of the Arians and Eunomians, maintaining that the Son was created out of nothing; that he had a will distinct and different from that of the Father, &c.

**EUDOXIOPOLIS**, in *Ancient Geography*, an episcopal town of Asia, in Pisidia.

**EUDOXUS**, the *Cnidian*, in *Biography*, was celebrated as an astronomer, a geometrician, a physician, and legislator, but was most particularly distinguished in the first of these characters. His first preceptor was Archytas, by whom he was instructed in the principles of geometry and philosophy: about the age of 23 he came to Athens. His knowledge of medicine is said to have been obtained in this way. A physician, named Theomodonus, observing the ardent desire which he manifested for study, notwithstanding his extreme poverty, presumed that he possessed talents which deserved cultivation, and therefore took him to his house, and afforded him every means of accomplishing his wishes, enabling him, as his own patrimony was small, to attend the schools of the philosophers, particularly that of Plato. Eudoxus afterwards went into Egypt, accompanied by a pupil, named Chrysippus, and here he was introduced by Agefilaus to king Nectanebis II., and by him to the Egyptian priests. He is highly celebrated by the ancients for his skill in astronomy; but none of his writings on this or any other subject are extant. Aratus, who has described the celestial phenomena in verse, is said to have followed Eudoxus; to whom is attributed the honour of bringing the celestial sphere and the regular astronomy from Egypt into Greece. Having left Egypt he taught astronomy and philosophy with great applause at Cyzicus, on the Propontis; and he afterwards removed to Athens, where he opened a school, and gained so high a degree of reputation,

reputation, that he was consulted on subjects of policy as well as sciences, by deputies from all parts of Greece. His death is generally referred to the first year of the 107th olympiad, 352 years before Christ. See Le Clerc. Hist. de la Med. Eloy.

Eudoxus is said by Fabricius (Bibl. Græc. lib. iii. c. 5.) to have written upon music, and he gathers from Theon of Smyrna, p. 94, that Eudoxus was the first who expressed the ratios of concords by numbers, and who discovered that grave and acute sounds depend on the slow or quick vibrations of the sounding body.

EUDRACINUM, in *Ancient Geography*, a town placed by the Itinerary of Antonine on the Alps, between Summus Penninus and Augusta Pætorina.

EUDRAPA, EDER, or *Edir*, a town of Asia, situated in Mesopotamia, W.S.W. from the town of Carmanda.

EUDROME, in the *Ancient Music*, the name of an air played by hautbois at the Sthenian games, instituted at Argos in honour of Jupiter. Hicorax the Argian was the inventor of this air.

EVE, the first woman, and mother of the human race. The history of her formation and other particulars is recorded in the Hebrew Scriptures (Gen. ii. iii. iv.); and it is needless to recite from Bayle and others the absurd fables invented concerning her by the Jewish rabbis.

EVE. See VIGIL.

EVEA, or EVA, in *Ancient Geography*, the ancient name of Byblos, a town of Phœnicia.

EVEA, in *Botany*, Aublet Guian. v. 1. 100. t. 39. Juss. 208. See CALLICOCCA, spec. 10.

EVECTION, in *Astronomy*, the most considerable of the lunar irregularities, and the first that was known to the ancient astronomers. It was discovered by Ptolemy. Its general and constant effect is to diminish the equation of the centre in the syzygies, and to increase it in the quadratures. If this diminution and augmentation were always the same, the evection would depend alone on the angular distance of the moon from the sun; but the absolute value of the evection depends likewise on the distance of the moon from the perigee of her orbit. After a number of trials and observations, it was found that this inequality could be represented very exactly by supposing it proportional to the sine of double the angular distance of the moon from the sun, minus the mean anomaly of the moon. The coefficient to this proportion is  $1^{\circ} 20' 30''$ .

The period of the evection differs but little from the periodic revolution of the moon: it is 27.178533 days. The evection is caused by the action of the sun upon the moon, and may be explained by supposing a change to take place in the excentricity of the moon's orbit, and at the same time a motion in the apogee.

Ptolemy supposed the epicycle of the moon to be carried along in an excentric circle, and that it was nearer to us in the quadratures than in the conjunctions and oppositions; so that to explain this inequality at the same time with the equation of the centre, he imagined an excentric and an epicycle. It is curious to trace the progress of these discoveries, and the history of the first observations of the evection has been transmitted in the words of Ptolemy himself. (Almagest. lib. v. cap. 1.)

In observing, says he, with care, the order of this inequality, we took notice that there was no other than the first and simple inequality in the conjunctions and oppositions, and even in the quadratures when the moon was in apogee or perigee, (meaning by the simple inequality the equation of the centre); but we may be assured that this is not sufficient to calculate the particular motion of the moon in other

aspects. The second inequality, (*i. e.* the evection,) is connected with the distance of the moon from the sun, and is re-established and disappears in the conjunctions and oppositions, and is greatest in certain quadratures. We discovered this inequality by the observations transmitted by Hipparchus, and by those which we have made by means of an instrument constructed for the express purpose of measuring the difference of longitude on the zodiac between the moon and the sun.

Ptolemy found that there was a difference of  $23^{\circ}$  between the observed and the calculated place (when the first inequality or equation of the centre was only used) when the moon in quadrature was three signs from the apsidæ. (Almagest. v. 3.) Then the sun being in the apogee or perigee of the moon, the inequality, which should have been  $5^{\circ}$ , was found  $7\frac{1}{2}^{\circ}$ ; to explain which he supposed the epicycle as above-mentioned.

Copernicus, to explain the evection, employed two epicycles. The small epicycle is supposed to describe the circumference of the great one in the space of an anomalistic revolution, and contrary to the order of the signs; while the moon describes the small epicycle contrary to the order of the signs in  $14^{\circ} 18'$ , or in the space of half a synodical revolution.

It was in this manner that the second inequality of the moon, called now the evection, was explained till the time of Tycho. It was called by Ptolemy "προσποσεισις, epicycli quasi annutum," by Copernicus "prosthaphæresim secundi vel minoris epicycli," by Tycho "prosthaphæresim excentricitatis," and by Bouillaud "evection," which name it still retains.

The evection was explained in a different manner by Horrox about the year 1640; but his theory was not made known till 1673, when Flamsteed calculated his new tables of the moon, upon the principles and numbers given him by Horrox. These tables were published in the posthumous works of Horrox in 1673. This hypothesis is the same with that of Arzachel, an astronomer who flourished in Spain in 1080, when that country was possessed by the Arabians, and who applied it to the motion of the sun. Let T be the centre of the earth (Plate XII. *Astronomy*, fig. 107.), C the mean place of the centre of the orbit which a planet is supposed to describe; so that TCA may be the line of the apsidæ, and TC the excentricity of the planet. If the centre of the orbit, instead of being fixed in C, be supposed to describe the circumference of a small circle ACB, there will result a double effect: 1. The line of apsidæ TA will change its position, and instead of remaining constantly in the direction TCA, it will pass, for example, into the position TG, and will make with the first position an angle ATG. 2. The excentricity, instead of being equal to the original quantity TC, will become TG, TB, &c. This hypothesis was invented by Arzachel to explain a supposed diminution of the excentricity of the sun's orbit, which he had inferred from some defective observations, and has not only been adopted by Horrox to deduce this inequality of the moon, but by Flamsteed, Halley, and Newton, for the same purpose.

Kepler had already announced that he employed an excentricity of the lunar orbit which varied every year; but Horrox was led likewise to this hypothesis by observations of the diameter of the moon; for about this time the application of micrometers to telescopes enabled astronomers to determine the apogee and perigee of the moon much more exactly than formerly. From these observations he perceived that the apogee of the moon was about  $25^{\circ}$  more advanced when the distance from the sun to the apogee

## EVECTION.

of the moon was  $45^\circ$  or  $225^\circ$ , than when it was  $135^\circ$  or  $315^\circ$ : hence the motion of the apogee, instead of being uniform, seemed to have an annual libration of more than  $12^\circ$ . This variation in the motion of the apogee being once known, its connection with a change of eccentricity was not difficult to be discovered. Both Halley and Newton employed the above hypothesis. According to the method of Newton the centre A of the orbit of the moon (*fig. 108.*) describes a circle ACB, the earth being at T. Thus TC expresses the mean eccentricity of the moon; TA the greatest eccentricity, and TB the least; TC being to CB as the mean eccentricity is to its difference from the least, or as the total sine is to the sine of  $12^\circ 18'$ , which is the greatest equation of the apogee. It is likewise supposed that if the angle ACG be taken equal to double the annual argument, or the distance between the sun and the mean apogee of the moon for a given time, the angle CTG will be the equation of the apogee, and TG the eccentricity for the same time. Then in the triangle TCG, the two sides and included angle being given, we have the sum of TC, and CG is to their difference as the tangent of half ACG, (or the annual argument, whose double is ACG,) is to the tangent of half the difference of the unknown angles. This is reduced to a constant logarithm, which added to that of the tangent of the mean annual argument, gives the annual argument corrected; and this, added to the place of the sun, gives the true place of the apogee of the moon. This is the form which Halley employed in his lunar tables.

It escaped the observation of Flamsteed, Halley, and Newton, that this equation might be calculated without supposing a variable eccentricity and libration of the apogee. Euler employed this method, of which the following is the demonstration.

Let L (*fig. 109.*) be the moon, T the earth, C the mean centre of the lunar orbit, G the centre for a given moment; CT the mean eccentricity of the moon, CLT the half of the mean equation of the orbit, because it is the double eccentricity which produces the whole equation; GLT the half of the evection for the time given, and represented in Newton's method by an augmentation of eccentricity; CLG is the difference of these two equations, or the effect which the change of eccentricity, and the libration of the apogee, produce upon the half equation. To find by a simple operation this angle CLG, which is the half of the evection, it must be remembered that when this angle is the greatest, or when LC is perpendicular to CG, the angle CLG is  $40'$ , that is, the constant relation between CL and CG is such, that the value of L can only be  $40'$  when it is the greatest, or  $1^\circ 20'$  for the whole evection. When the angle LCG is oblique, the angle CLG will diminish, and that in the ratio of the perpendicular GD to the line CG, or as the sine DCG to radius. Hence the evection will be  $80'$  sin. DCG; but the angle DCG = ACL - ACG is the mean anomaly of the moon, minus twice the distance of the sun from the moon's apogee, or what is the same, twice the distance of the moon from the sun, minus the mean anomaly of the moon, which forms the argument of evection.

The half evection, or angle GLC, is equal  $40'$  sin. (2 dist.  $\odot$  - m. anom.  $\text{D}$ .) This is the form in which it is usually found in the lunar tables.

When we come to treat of the theory of the moon, and the lunar inequalities, we shall have occasion to resume this subject, and to shew how correctly this equation is derived from the law of universal gravitation; we shall confine ourselves at present to a very general explanation of the physical cause of this phenomenon.

VOL. XIII.

When the sun corresponds to the apogee or perigee of the moon, that is, when the line of apsidæ of the moon coincides with the line of the syzygies, the central force of the earth upon the moon, which is the weakest in the syzygy apogee, receives the greatest diminution, and the central force, which is the strongest at the syzygy perigee, there receives the least diminution, therefore the difference between the central force perigee and the central force apogee will then be the greatest, and the difference of the distances will be augmented, that is, the eccentricity will become greater, and observation shews that the equation is then  $7^\circ 40'$ , whereas it does not exceed  $5^\circ$  when the line of the quadratures coincides with the line of the apsidæ.

The formula for the evection in the latest tables is  $1^\circ 20' 28''$  sin (2 dist.  $\odot$  - mean anomaly  $\text{D}$ ); from which it is easy to follow the successive variations of this equation, for it is only requisite to consider the different values which its argument can take. If it be required, for instance, to determine when it arrives at its maximum, we have only to investigate the case in which the angle 2 dist.  $\odot$   $\text{D}$  - m. anom.  $\text{D}$  becomes equal to  $90^\circ$ , or  $270^\circ$ , or its sine equal to unity, the evection will then be equal  $1^\circ 10' 21''$ : the first of these values will happen in the quadratures, when the mean anomaly is equal  $90^\circ$ , for then 2 dist.  $\odot$  =  $180^\circ$  2 dist.  $\odot$  - m. anom.  $\text{D}$  =  $180^\circ - 90^\circ = 90^\circ$ ; on the contrary, the evection will disappear, when the argument is zero or  $180^\circ$ , this will happen in the syzygies when the moon is either perigee or apogee, for then the distance of the moon from the sun is equal  $0^\circ$  or  $180^\circ$ , and the same of the mean anomaly. But by the various combinations of the two angles which form the argument of evection, the greatest and least values will arrive, even in several other points of the orbit. In general, in the conjunctions, the evection will have a contrary sign to the equation of the centre, for its argument is reduced to - mean anom.  $\text{D}$ , which gives a negative sign if the anomaly is less than  $180^\circ$ , and a positive sign if it is greater; but in the first case the equation of the centre is additive, and in the second it is subtractive. It is easy to comprehend that it will be the same in the oppositions, hence it follows that in the syzygies the evection is subtractive from the equation of the centre, on the contrary it is additive in the quadratures. Thus the first observers that examined the theory of the moon's motion only by means of eclipses, and with no other view but to predict those phenomena, always found the equation of the centre too small, by the quantity of the evection in the syzygies.

It is not difficult to find the period of the evection from the variations of the value of the angle on which it depends; it is sufficient to calculate the variations of this angle in a given time; and to conclude, by a simple proportion, the number of days necessary for it to vary  $360^\circ$ .

The synodical motion of the moon in one century is  $445267^\circ 6' 55''.46$ , multiplying this by two, we have  $890534^\circ 13' 50''.92$  for the double of the distance of the moon from the sun, after a hundred Julian years. If from this we take the anomalous motion of the moon, in the same interval, or  $477198^\circ 41' 30''.6$ ; the difference  $413335^\circ 32' 20''.3$  will be the value of the argument of evection, after 100 Julian years; from whence it appears, that this argument increases  $360^\circ$  in a number of days expressed by  $360.36525$ , or  $27.178533$  days; this is the period of the evection, after which period it successively takes again the same values.

From this it appears, that substituting, instead of these angles, their values calculated as above, the argument may be put in the form of a quantity proportional to the time;

for example, if we name the number of days elapsed since a given epoch as that of the tables  $t$ . The angle  $z$  di.  $D \odot$  —  $m$ . anom.  $D$  will become  $\frac{t \cdot 360}{27.178533}$ , and the evection may be represented under this form  $1^\circ 20' 28'' \left( \frac{360 \cdot t}{27.178533} \right)$  or simply  $1^\circ 20' 28'' \sin. m. t.$  making  $m = \frac{360}{27.178533}$ .

EVEILLON, JAMES, in *Biography*, was born at Angers in the year 1542; he was distinguished at a very early age for his literary acquirements, and obtained considerable ecclesiastical preferment, in the place of his birth, till at length he was made grand-vicar to the bishop. Eveillon was looked up to for his superior knowledge of the rights and usages of the church; and of every subject connected with the councils, the fathers, and the canon law. He was not unfrequently employed in matters relating to church discipline, the reformation of breviaries, rituals, and monastic institutions. His principal works were entitled "De Proceffionibus Ecclesiasticis, in quo earum Institutio, Significatio, Ordo, et Ritus explicantur."—"De reſta Pallendi Ratione;" and "A Treatise on Monitions and Excommunications," which has borne a high character in the Catholic communion. Eveillon died at the age of 79, in the year 1621. He was a man of extensive benevolence, having obtained the title of father to the friendless, and the poor, to whose relief he devoted the whole of a liberal income, excepting what was absolutely necessary for his own support. Moreri.

EUELPIDIUM, a kind of fluid collyrium.

EUELPISTI, a plaster described by Scribonius Lar-gus.

EVELYN, JOHN, in *Biography*, the son of Richard Evelyn, esq. was born at Wotton, in Surrey, in 1620. He received the early part of his education at Lewes, from thence he went to Christ church, Oxford. During the civil wars he spent his time on the continent, particularly in France and Italy. He married in the year 1647 the only daughter of sir Richard Browne, the king's minister at Paris, and returned to England about the year 1651, where he employed himself in literary occupations, chiefly in translating from the French and Latin. He was much inclined to a life of learned leisure; and in his zeal to forward a similar plan for others he formed a scheme for the erection of a college, where persons might live together in philosophical retirement, and in the pursuit of common studies. In 1657 he published a favourable account of the king's character, with a view of preparing his countrymen for the restoration of monarchy, and on the return of the exiled Charles, he was graciously received, and introduced into public life, though without abandoning his literary pursuits. In 1662 he published a curious and learned work, containing much useful and important information, entitled "Sculptura, or the History and Art of Chalcography, or Engraving on Copper." This piece was reprinted in 1755, with additions. Mr. Evelyn practised the art himself, and is introduced by Mr. Walpole into his catalogue of English engravers. On the institution of the Royal Society, he was nominated among the first fellows and members of the council, and he ever after continued a zealous and truly active member of that learned body. At some of the early meetings of the society was read his discourse on forest trees, which was the basis of the treatise entitled "Sylva, or a Discourse of Forest Trees, and the propagation of Timber in his Majesty's Dominions, to which is

annexed Pomona, or an Appendix concerning Fruit Trees, in relation to Cyder, &c." As a sequel to this work, he afterwards published his "Terra, a Philosophical Discourse of Earth, relating to the Culture and Improvement of it for Vegetation, and the Propagation of Plants." Both these works have been reprinted several times. The edition of the Sylva by Dr. Andrew Hunter, of York, is with plates of all the trees, in which their parts of fructification are accurately displayed according to the Linnæan system. Mr. Evelyn was appointed, at the desire of the king, in 1664, one of the commissioners of the sick and wounded seamen, and likewise a commissioner for rebuilding St. Paul's cathedral. How well fitted he was for the latter office was shewn by a work which he published, entitled "A Parallel of the Ancient Architecture with the Modern," translated from the French of Roland Freart, sieur de Chambray; with additions from Alberti and others. He resided at this period at his house of Sayes-court, near Deptford, which he had in right of his wife; here he cultivated a garden, and was regarded as a great improver of the art of horticulture and celebrated for the pains which he took in the introduction of exotics into this country. During the reign of Charles, a board of trade was formed, and Mr. Evelyn was appointed one of its members. On this occasion he drew up a small treatise on the origin and progress of navigation and commerce, with an assertion of the king's title to the dominion of the sea. Among the papers which he communicated to the Royal Society is a curious letter, given at length in the *Biographia Britannica*, describing the mischiefs done to his garden by the severe winter of 1683—4. This letter will be read with interest, as affording information of the perennials at that time chiefly cultivated in England, and as stating the dire effects of rigorous frost. We shall give the concluding paragraph:

"The vines have escaped, and of the esculent plants and sallads, most, except artichokes, which are universally lost; and what I prefer before any sallad whatever, eaten raw when young, my sampier is all rotted to the very root. The arborescent and other sedums, aloes, &c. though housed, perished with me, but the yucca and opuntia escaped. Tulips, many are lost, and so the Constantinople-narcissus, and such tuberosæ as were not kept in the chimney corner, where was a continual fire. Some anemonies appear, but I believe many are rotted. My tortoise, which by his constant burying himself in the earth at the approach of winter, I looked upon as a kind of plant animal, happened to be obstructed by a vine-root from mining to the depth he was usually wont to inter, is found stark dead, after having many years escaped the severest winter. Of fish I have lost a few, and the nightingales, which for being a short winged bird, and so exceedingly fat at the time of the year, we commonly suppose them to change the climate, whereas indeed they are then hardly able to fly an hundred yards, are as brisk and frolic as ever; nor do I think they alter their summer stations whatever may become of them all the winter."

In the reign of James II. Mr. Evelyn was, during the absence of the earl of Clarendon in Ireland, made one of the commissioners for executing the office of lord privy seal, and after the revolution he was appointed treasurer of Greenwich hospital. In 1697 he published a discourse on medals, entitled "Numismata, &c." and his last work was "Acetaria, a Discourse of Sallets," in which he treats of the nature and properties of all plants which have been employed as sallad herbs. This discourse was inscribed to lord chancellor Somers. The dedication, which is written with

much elegance, was intended to procure, if possible, a public establishment for the Royal Society. Mr. Evelyn died in Feb. 1706 in his 86th year, having passed his days in useful and elegant pursuits, and distinguished by benevolence, piety, and integrity. *Biog. Brit.*

EVELYN, JOHN, son to the former, was born Jan. 14, 1654, at his father's house at Deptford. He was at a very early age admired for his rapid progress in knowledge, so that in the year 1666 he was sent to Oxford under the special care of Dr. Bathurst, till he could be admitted a gentleman commoner, which was in the Easter term, 1688. It does not appear that he took his degrees there, but returned to his father's house, where he prosecuted his studies with much diligence and success. During his residence in Trinity college, he is supposed to have written the elegant Greek poem which is prefixed to the second edition of the *Sylva*. He became deeply learned in the ancient and modern languages, and cultivated poetry, of which there is evidence by a translation "Of Gardens, first written in Latin by Renatus Rapinus." This was published when the translator was a youth of nineteen years of age only. He afterwards translated Plutarch's life of Alexander the Great from the Greek; and from the French he gave a translation of "The History of the Grand Viziers, Mahomet, and Achmet Coprogli." He was likewise author of several poems, two of which have been chiefly admired, the one "On Virtue," and the other was entitled "The Remedy of Love," and have been inserted in Dryden's *Miscellanies*. Mr. Evelyn was a man of business as well as a cultivator of literature, and was appointed one of the commissioners of the revenue of Ireland. He died in the prime of life, in London, March 24, 1698, in the forty-fifth year of his age, leaving behind him two sons and three daughters. *Biog. Brit.*

EUE'MBOLOS, (from *eu*, *well*, *eu*, *in*, and *βωλλω*, *to cast*,) a person skilful in setting bones.

EVEN FOOT, in *Poetry*. See FOOT.

EVEN number, is that which may be divided into two equal parts or moieties. See NUMBER.

EVENELADS, in *Geography*, a river of England, in the county of Oxford, which runs into the Isis, about 5 miles W. of Oxford,

EUNES, a town of Norway, 18 miles N. of Drontheim.

EVENING STAR, in *Astronomy*. See VESPER.

EVENING island, in *Geography*, a small island in the Pacific ocean. N. lat. 2° 46'. W. long. 133° 17'.

EVENLY even number, is that which is exactly divisible by an even number taken an even number of times; such is 32, since it is divisible by 8, taken four times.

EVENLY odd number, is that which an even number measures by an odd one; as 30, which is measured by 6, taken five times.

EVENUS, in *Ancient Geography*, a river of Asia Minor, according to Pliny, who says that the towns of Lyrnessa and Miletus were built upon its banks. The inhabitants of Adramyttium drew water from this river by means of canals. Strabo.

EVENUS, *Fidari*, a river of Greece, in *Ætolia*, which took its rise towards the north-east in mount Pindus, on the frontiers of Thessaly, and passing through the territories of the Bomizei, Ophientes, and Apodoti, watered Calydon, and discharged itself into the sea; to the west is the town called Chalcis. It was on the banks of the Evenus that Hercules, according to the fable, slew the centaur Nessus.

EVERARD'S sliding rule. See SLIDING.

EVERBODE, in *Geography*, a town of France, in the department of the Dyle; 5 miles N. of Diest.

EVERDINGEN, CÆSAR VAN, in *Biography*, a painter of histories, portraits, and landscapes, born at Alkmaer in 1606. The master under whom he studied, Van Bronckhorst, soon observed and encouraged his superior talents from among the rest of his disciples. He had a lively invention, and painted with freedom and firmness, and a good force of colouring.

Many of his pictures are spoken of in terms of praise; but the one selected as his principal performance is the representation of the victory of David over Goliath. It was painted on the folding doors of the organ in the great church at Alkmaer; and the sketch of it was preserved in the council chamber of that city; it was painted in 1648. He died in 1679, aged 73.

EVERDINGEN, ALDRET VAN, a landscape painter, whose merit was very considerable. He was the nephew of Cæsar Van Everdingen, and was born in the same city, Alkmaer, in 1621. Having first attended to the instructions of Roland Savery, he afterwards greatly improved by those of Peter Molyn; whom at last he surpassed in skill. He delighted most in the grand scenes of nature, or rather her more romantic features, such as rocks, torrents, and cataracts, which he executed with great freedom and variety of touch. In his time he had no superior, but Jacob Ruyssdael followed him immediately, was indeed partly contemporary with him, and in his own style left him far behind in the brilliancy and force of his colours and execution, and the choice of his forms. However, Everdingen is highly deserving of great praise for the care which he took to make himself acquainted with the effects of nature, and the truth with which he marked them. He made a voyage up the Baltic, and was much gratified by and made much use of the scenery, which the romantic coasts of that sea, and of Norway, (which he also visited) afforded him. He died in 1675, and left behind him a great number of drawings, both of real views and compositions, which are very freely wrought. He was thought not to succeed so well in large works as in smaller ones, those coming more within the management of the neatness of pencilling, which characterizes his style of execution. The latter are very highly and very deservedly valued in Flanders and Holland.

EVERDINGEN, in *Geography*, a town of Holland, in Guelderland; three miles W. of Culemburg.

EVERET'S BRIDGE, a place of Nansemond county, in Virginia; where is a post-office; 266 miles from Washington.

EVERGEM, a town of France, in the department of the Escaut, and chief place of a canton in the district of Gand. The place contains 6878, and the canton 13,176 inhabitants, on a territory of 67½ kilometres and four communes.

EVERGETÆ, in *Ancient Geography*, a people of Asia, placed by Strabo in the vicinity of Diargiana.

EVERGETES, *Ευεργέτης*, a Greek term, signifying benefactor, being formed of *eu*, *well*, and *εργον*, *opus*, *work*. It is still retained in our language by way of addition or epithet given to two princes or kings of Syria and Egypt, who succeeded Alexander. Thus we say Ptolemy Evergetes, king of Egypt, Antiochus Evergetes king of Syria.

EVERGREEN THORN, in *Gardening*. See MESPILUS *Pyracantha*.

EVERGREEN Trees, are such trees, whether of tall or shrubby growth, as constantly retain their leaves during the whole year. There is a great number of this sort of

plants, which will be particularly described under their proper genera.

These kinds of trees, shrubs, &c. are increased in different modes, according to their particular nature, as by seeds, layers, cuttings, suckers, &c. which is fully shewn under the culture of the different sorts, but principally in the spring season, though occasionally in the summer, and frequently in the early autumn.

The proper seasons for planting them out are the early autumn or latter spring months, according to the nature of the soil. Where the soils are of the more stiff, retentive, moist kind, the more advanced spring months are the best; but where they are of the light, dry, loose description, the beginning of the autumn is the most proper period; as in the former case the plants will be in no danger of being injured by stagnant moisture in the winter, and in the latter there will be no risk of their being destroyed by the heat and dryness of the summer, before they become perfectly established in the ground.

In the planting of evergreen trees, it is seldom necessary to put them into any great depth, as they are very liable to be destroyed by deep planting. There is likewise another circumstance that ought to be regarded, which is that of having the mould in which they are to be set sufficiently fine, and the roots well bedded in it, without being too much cut in or retrenched. In all cases the loose mould should be well trodden in about them; and the more tall growing kinds well supported with strong stakes, so as to keep them perfectly steady in their situations. Numbers of trees of this, as well as other sorts, are destroyed for want of attention in this respect, as when once they get loose they soon die by the motion which takes place. The pruning or cutting in of this sort of trees, where it is necessary, should be performed either in the more advanced spring season, or the latter part of the summer, but never in the winter season, as they are liable to much injury from cold. This is equally necessary to be regarded in the clipping of hedges constituted of plants of this sort.

Many of these sorts of trees and shrubs are sufficiently hardy to admit of being planted in most sorts of soils and situations. The tall-growing kinds are well adapted for affording ornament and variety in mixture with those of the deciduous class in extensive plantations, and such as are of a shrubby growth in the borders, clumps, and other parts of ornamented grounds. In these situations they should be suffered as much as possible to take their natural growth, especially the fir kinds, and in the others only very little cut in, and the dead wood removed from them.

In the forming of hedges various plants of this sort are employed; but the best are those of the holly, yew, evergreen privet, and box kind; though the common laurel and laurustinus may be the most adviseable, where they are required to be lofty. These are likewise capable of being trained so as to cover naked walls, palings, or other unpleasant objects. Hedges formed of these plants should be clipped once or twice during the summer season, so as to keep them in perfect neat order.

Various ornamental devices were formerly made with these and other sorts of evergreens in gardens; but these are at present little in use, as a better and less troublesome taste prevails.

It has been remarked by the author of "The Philosophy of Gardening," that in these sorts of trees and shrubs the buds rise in the bosoms of the leaves, which, as they are not shed in the autumn, continue to oxygenate the juice of the plants, and supply nutriment to the buds during the fine days in the winter and spring seasons, surviving till

nearly the middle of summer, when the new buds have expanded leaves of their own. It is hence conjectured, that evergreens provide no store of nourishment in their roots, or albumen in the summer for the support of their ensuing vernal buds, and of course have probably no bleeding season, as is the case with those of the deciduous kind.

And there is another circumstance which has been stated by Dr. Milae, in his botanical dictionary, to take place in respect to evergreen trees, which is, that when they are engrafted on those of the deciduous sort, it determines the latter to retain their leaves. This is asserted to be confirmed by repeated experience, in grafting the laurel, (*lauro-cerasus*) an evergreen, on the common cherry, (*cerasus*), and the (*ilex*), an evergreen oak, on the common oak. And it is probable that many other facts of the same kind may exist, though they have not been noticed by common gardeners.

EVERLASTING. See GNAPHALIUM.

EVERLASTING Pea. See LATHYRUS.

EVERLASTING Pea, in *Agriculture*, is the common name of a perennial plant of the vetch kind, which grows naturally in some situations in this country; and is capable of being cultivated with great care and advantage as a green food for cattle or other stock, where the soils are inclined to be of the more heavy loamy kinds; as it affords a large produce of the most nutritious sort of fodder. Where it is suffered to stand till the seeds are formed, it has been found in the few trials that have been made with it to possess a highly fattening property when consumed by animals.

EVERRIATOR, derived from *ex* and *verro*, *I cleanse*, in *Antiquity*, an officer who was obliged in a solemn manner to cleanse such houses as were defiled by dead bodies, called *domus funestæ*.

EVERRICULUM, (from *everro*, to sweep away,) a kind of instrument, in *Surgery*, resembling a spoon, and used for taking away any small fragments of the stone, which may remain behind in the bladder, in the operation of lithotomy.

EVERS, in *Rural Economy*, a term sometimes provincially applied to those stiles which open; in which case the top rail has a bolt of iron driven through it at one end, the other falling into a notch in the opposite post, by which contrivance an opening can occasionally be readily made.

EVERSBERG, in *Geography*, a town of Germany, in the kingdom of Westphalia; 34 miles N. of Cologne.

EVERY YEAR'S LAND, in *Agriculture*, is a term applied to such lands as have been cropped with what are termed brown and white crops, or pulse and grain crops, in alternation or succession for a very great length of time, without the intervention of any sort of fallow. Mr. Marshall has remarked that extensive common fields in Gloucestershire have been conducted under this sort of management for "perhaps centuries;" and the same is the case in some other countries.

EVES-DROPPERS, in *Law*. See EAVES-DROPPERS.

EVESHAM, or ESAM, in *Geography*, is a borough and market town, pleasantly situated upon a rising ground, above the banks of a navigable river, named the Warwickshire Avon, in the hundred of Blakenhurst, and county of Worcester, distant from London ninety-six miles. This place claims high antiquity, and is not less notable for its subsequent celebrity. The first notice of it upon record, like the origin of most towns referable to the Saxon period, is the account of Egwin, bishop of Worcester, having founded a monastery here in the year 709; and amply endowed it by the assistance of Kenred, son of Wulpher, king of Mercia. This was one of the mitred abbies; its abbot

## E V E S H A M.

fat in the house of peers as a baron of the realm; its privileges were numerous and extensive, and the revenues on the dissolution were valued at the annual sum of 1183*l*. Of the building, which from records appears to have been immense, few vestiges remain. The large elliptical arch, decorated with rich but mutilated imagery, is still standing; and the tower noticed by Leland. "Clement Lichfield the last abbot of Evesham gave one, did very much cost in building of the abbey and other places longing to it.—He made a right sumptuous and high square tower of stone in the cemetery of Evesham. This tower had a great bell in it, and a goodly clocke, and was as a gateway to one piece of the abbey." Itinerary, vol. iv. p. 108. This tower is a regular and beautiful structure, twenty-two feet by twenty-two, and one hundred and seventeen in height; and is generally considered the last monastic building erected under papal influence in England. Though the churches have towers, this still continues the station for the clock and bells.

In that part of the town called Bengeworth, which may be viewed as a suburb on the eastern side of the river, over which the communication is formed by a handsome stone bridge of seven arches, stood an ancient castle, probably erected soon after the Norman conquest. For in the year 1152, abbot William de Audville gained this fortress from lord William de Beauchamp, who held it for king Stephen, razed it level with the ground, and converted the site into a place of interment.

Evesham is a very ancient borough, enjoying numerous privileges, both by prescription and charter. It was one of the towns summoned by writ to send members to parliament, in the twenty-third year of king Edward the First's reign, when he basely pretended to restore the Saxon constitution; and was one of the eight boroughs which had their elective franchise restored in the time of James the First. That monarch at the same time granted a charter to the town to be governed by a mayor, seven aldermen, twelve burgesses, and twenty-four assistants, recorder, chamberlain, who are also of the common council, and other subordinate officers. The mayor and four senior aldermen are justices of the peace, form a *quorum*, and have power to hold a sessions of *oyer* and *terminer*, and gaol delivery, to punish all crimes, except high treason, and execute felons within their liberty.

The town is much altered since Leland visited it; the houses, which then were what are called *half-timbered*, that is, timber frames, having the open parts filled up with wattle and dab, are mostly well built with brick, the streets are wide and spacious, and the salubrity of the air, with the beauty of the situation, induce many genteel families to take up their residence here. In the town are three parish churches, two in the part usually called Evesham, and one in Bengeworth; a well endowed free grammar school, charity school, and alms-house. The market, held on Mondays, is well supplied, and four annual fairs are held February the second, the first Monday after Easter, Whit-Monday, and the twenty-first of September. From the late returns to government under the Population act, the number of houses appear to be 616, and of inhabitants 2837. The richness of the soil in the vicinity has been long an inducement to turn many of the fields into garden ground, and the peculiar fineness of the vegetable productions of this place has rendered Evesham gardeners proverbial for unrivalled skill. They not only supply the neighbourhood, but also the city of Worcester, fourteen miles distant; Birmingham, thirty; and during the asparagus season Bath and Bristol, more than fifty. Tindal's History and Antiquities of Evesham.

**E V E S H A M, Vale of.** The finest tract of land comprized under this denomination, unrivalled in fame or fertility, is situated on the eastern and western banks of the river Avon, extending for several miles in various directions into Warwickshire, where it is bounded by the high land of the Ridgeway, and into Gloucestershire, where the Cotswold hills form a terminating barrier; and the south is washed by the river Severn.

It is described in Monastic history as having derived the name, which it gives to the town already described, from *Eoves*, a Saxon, a wine-herd to Egwin bishop of Worcester, in the latter end of the seventh century: this ham having been Egwin's property till he was dethroned by the pope, and his estates confiscated. Previously to this it was called *Heth-holme*, or *Heath-field*.

To those who wish to see what "sun and soil," unassisted by art, can do, parts of this district will furnish striking specimens. And to the admirers of agriculture other portions will evince what wonders may be effected from aiding the efforts of nature by the application of art. The soil is principally a deep heavy loam, or rich loamy clay, of inexhaustible depth, equally calculated for corn, or pasturage. And whether it be placed under an arable, or a grazing system, the produce and the profits alike exceed analogical belief. The vale of Evesham, says Leland, "is, as it were, for such an angle, the horreum of Worcestershire, it is so plentiful of corn;" and justly has he characterized this prolific spot. For the abundance of herbage is not equalled by the famous Tilney meeth in the hundred of Marshland and county of Norfolk; nor can the crops of corn be surpassed, except by those described in Brydone's Tour as produced in the vales of Sicily. The rent of lands in the farms of this district is equal to that of accommodation lands in most other parts of the kingdom; yet persons who have occupied estates in some others, at an exceeding low rate on a comparison of the net proceeds from both, do not hesitate in deciding in favour of the higher rental. In this vale, about a mile distant from the town of Evesham, was fought the most memorable battle recorded in the annals of English history, between Simon de Montfort, the powerful earl of Leicester, and prince Edward, afterward king Edward the First; in which the earl was completely defeated, and the refractory barons, with most of their adherents, taken or slain. He has been not unaptly compared to the Roman conspirator Catiline, for, like him, he verified in his conduct the remark of Tiberius, recorded in Tacitus Ann. l. iv. c. 18. "Beneficia eo usque lata sunt, dum videntur exsolvi posse." "Favours are only so long properly bestowed as there appears a probability, or at least a capability of return." After king Henry the Third had conferred upon him an accumulation of honours and emoluments, and even permitted him to marry the princess, his sister; he experienced from the earl the most ungrateful requital. He pursued the monarch with the most inveterate hatred; and by inflammatory speeches, and other overt acts, excited the most perplexing commotions, and distressing intestine warfare, the kingdom ever experienced; under a pretence of restraining the prerogative, reforming the government, and ascertaining and securing the liberties of the subject. The contest, however, was productive of good, intended by neither of the parties. The prince, when he had ascended the throne, determined to still further curtail the enormous power of the barons; and by his writs summoned together, as his advisers, representatives from numerous cities and boroughs, as well as counties; the battle of Evesham therefore may be considered "as the origin of our present house of commons."

**E V E S H A M**, a township of America, in Burlington county, New

New Jersey, situated between the forks of Moore's creek, which runs north-westerly to Delaware-river; 16 miles E. of Philadelphia.

**EVESPERIDES**, in *Ancient Geography*, a people of Africa, in the maritime part of Libya, to the west of the Aufchifes: whose country, according to Herodotus, was singularly fertile; whence it has been supposed that the famous garden of the Hesperides was found in their territory. This name, in its grammatical acceptation, signifies Occidentals.

**EVESPERIS**, a town on the coast of Africa, which afterwards took the name of Berenice.

**EVEST**, in *Geography*, a river of Russia, which runs into the Dwina, near Kreutzburg.

**EUEXIA**, from *eu*, well, and *εξω*, habit, in *Medicine*, a good sound habit of body.

**EUFEMIA**, **ST.**, in *Geography*, a town of Naples, in the province of Otranto, two miles N.N.E. of Alessano.—Also, a town of Naples, in Calabria Ultra, situated on a bay of the Mediterranean, to which it gives name. N. lat. 39° 2'. E. long. 16° 30'.

**EUFRA**, a town of South Finland; 12 miles N.N.E. of Abo.

**EUGALENUS**, **SEVERINUS**, in *Biography*, a physician of Doccum, in Friesland, known chiefly as the author of a treatise on the scurvy, which once maintained a considerable character, and passed through many editions. Its title is "De Scorbuto Liber, cum Observationibus quibusdam, brevique et succinctâ cujusque curationis indicatione, 1604." But the treatise of Dr. Lind, on the same subject, in which the absurdities and ignorance of Eugalenus are pointed out, has superseded it. Eloy. Mangeti Bibl. Script. Med.

**EUGANEI**, in *Ancient Geography*, a people of Italy, towards the Alps.

**EUGANO**, in *Geography*, a mountain of Italy, in the west part of the Paduan, bordering on the Vicentin.

**EUGENE**, **FRANCIS**, of Savoy, in *Biography*, generally denominated prince Eugene, grandson of Charles-Emanuel, duke of Savoy, was born at Paris in 1663, and destined for the church. His mother, on account of her ill-conduct, was obliged to leave Paris. She retired to Brussels, and young Eugene being deprived of her support, and having been disappointed in his expectations of preferment, went as volunteer to serve in Germany against the Turks. He, with other French volunteers, was recalled on pain, in case of disobedience, of perpetual banishment. He set the order at defiance, and so much distinguished himself in his first campaign, that the emperor gave him a regiment. After the siege of Vienna was raised, he served in Hungary under the command of the duke of Lorraine and the elector of Bavaria. From this time his reputation increased, with every action in which he engaged, till, in the year 1697, he was appointed to the command of the imperial army. In the autumn of this year he entirely defeated the Turks at the battle of Zenta, in which the grand vizier and more than 20,000 men were left on the field, and the grand seignior was obliged to make a precipitate retreat with the broken relics of his army. Eugene had hazarded this engagement contrary to the express orders of the imperial court; but he so completely justified his conduct, that Leopold gave him a written authority to act thenceforth according to his own judgment. He was now opposed by all the great French generals, but in every battle his exertions and prowess were crowned with success, and on returning to Vienna the emperor created him president of the council of war, and entrusted the military chest to him; but that chest was

frequently ill supplied, which occasioned him more trouble than the most vigorous opposition in the field. He was strictly united with the duke of Marlborough, and by their talents and concert they obtained a decisive superiority over the French in Germany. At the celebrated battle of Blenheim, Eugene commanded the imperial part of the army; and had no small share in the success. In 1705, he was defeated in Italy, but in the following campaign he regained his reputation by marching across Lombardy in the face of the French army, and attacking the French in their intrenchments at Turin, over whom he obtained a complete victory, which secured the duke of Savoy and restored all the Milanese to the emperor. In 1707, he invaded France, but without obtaining any decisive advantage, and in 1708 he was with the duke of Marlborough at the battle of Oudenard, and the capture of Lisle. He commanded the centre at the bloody battle of Malplaquet, where he was grievously wounded, but refused to retire from the field, saying, "Of what use will it be if we are to die here;—if we are to survive it will be time enough in the evening to be dressed." When the politics of England took a turn and peace was determined on, Eugene carried on the war alone, till it was concluded by the peace of Radstadt in 1714. Shortly after this he was called on to contend again with the Turks, whom he signally defeated in the year 1716. In the following year he undertook the siege of Belgrade, when the Turks came to its relief, and invested him in his camp. He suffered them to approach very near, and then suddenly quitting his lines fell upon them with so much vigour, that he killed 20,000 men, and possessed himself of their cannon and camp equipage. Belgrade immediately surrendered, and an advantageous peace was the result of this important victory. Eugene now retired to Vienna covered with glory, and justly considered as the saviour of the empire, and the greatest benefactor to the house of Austria: He was great in retirement, as he had been heroic and magnanimous in war. In the year 1733 he attempted new exploits, in consequence of the disputed election to the Polish crown; but he was no longer the great, the enterprising Eugene. He died in 1736 at Vienna, aged seventy-three. As a man he was cold and reserved in his manner, and serious in his aspect: as a friend he was liberal, free from pride, faithful to his promises, and ever ready to do a kind action. As a general he was regarded by those under him in the character of a father and protector: in his military capacity he was enterprising, full of resources, and though he sometimes committed faults, he rarely failed to redeem his credit by new and brilliant successes. Moreri. Modern Universal Hist. Hist. of England. See also the article **CHURCHILL** in this Dictionary.

**EUGENIA**, in *Botany*, so named by Micheli in compliment to the heroic prince Eugene of Savoy, who sent him from Germany almost all the plants described by Clusius, and who had a celebrated botanic garden. Mich. Gen. 226. t. 108. Linn. Gen. 247. Sm. Tr. of Linn. Soc. v. 3. 280. Schreb. 333. Willd. Sp. Pl. v. 2. 959. Mart. Mill. Dict. v. 2. Juss. 324. (Syzygium; Gærtn. t. 33.). Class and order, *Icosandria Monogynia*. Nat. Ord. *Hesperideæ*, Linn. *Myrti*, Juss.

Gen. Ch. Cal. Perianth superior, in four deep, oblong, obtuse, concave, permanent segments, the orbicular centre between them elevated, and somewhat downy. Cor. Petals four, twice as large as the segments of the calyx, oblong or roundish, obtuse, concave. Stam. Filaments numerous, inserted into the elevated ring of the calyx, about as long as the corolla; anthers small, roundish. Pist. Germen inferior, turbinate; style simple, the length of the stamens; stigma

stigma simple: *Peric.* Berry roundish or angular, crowned with the calyx, of one cell. *Seed* solitary, roundish, smooth and even.

*Eff. Ch.* Calyx superior, in four deep segments. Petals four. Berry of one cell, with one seed.

*Obf.* The number of petals, and segments of the calyx, is frequently five, in one instance eight. The germen has, in some species at least, two cells, though one of them becomes obliterated as the fruit ripens.

This is an extensive genus, chiefly from the East and West Indies, whose species are as difficult to define as the roses in our European gardens. Their habit is akin to the myrtle, but often more stout and arborefcient. *Leaves* simple, opposite, ovate or elliptical, entire, without stipulas, most frequently smooth, paler beneath, evergreen. *Flowers* either terminal or axillary, white or reddish. *Fruit* not unwholesome, but scarcely ever very grateful to the palate; in some cases highly fragrant. Willdenow has 30 species, a number far short of what are known, and yet two of them (*acutangula* and *racemosa*), are scarcely true *Eugenia*. There is also some confusion between this genus and *Plinia*, the original *E. uniflora*, Linn. Sp. Pl. 673, being not only *Myrtus brasiliensis*, *ibid.* 674, but also *Plinia rubra*, Linn. Mant. 243; as well as *P. pedunculata*, Linn. Suppl. 253; under which last name it is figured in Curt. Mag. t. 473, with a wrong quotation of Linn. Mant. Whatever the *Plinia* of Plumier may be, this plant is the original *Eugenia* of Micheli's figure, and is well known in the Brasils and West Indies, its fruit resembling an indifferent cherry in size, taste, and colour, though different in being externally furrowed. This fruit sometimes ripens in stores in England, but the plant is no general favourite, being a meagre representative of the common myrtle.

*E. Jambos.* Linn. Sp. Pl. 672. (Malacca Schambu; Rheede Hort. Mal. v. 1. t. 17.), is much celebrated for the fragrance of its fruit, which resembles that of a rose, or rather rose-water. It is also of an extremely fine yellowish colour with a rosy tint, and though not pleasant to the taste, is frequently brought to table in the Indies, for the sake of its perfume.

*E. malaccensis.* Linn. Sp. Pl. 672. Sm. Exot. Bot. t. 61, a beautiful East Indian species, is esteemed for the elegance of its red clustered flowers, as well as the flavour and cooling quality of its fruit.

**EUGENIUS I.** in *Biography*, pope, was born at Rome, and raised to the highest dignity in the church in the year 634, on the deposition of pope Martin. He owed his elevation to the choice of the Roman people and clergy, and their choice was confirmed by the emperor Constans. At this period the western and eastern churches were furiously contending with each other upon the question whether Christ possessed one will or two. Eugenius, after his promotion, took pains to quiet the minds of the disputants. A compromise was entered into between the parties, but it was not of that nature to command general approbation: it was unsatisfactory to the Roman people and clergy, who opposed the admission of the patriarch Peter's confession of faith. Peter had taken the other side of the question, and in his confession he took no notice of the will and operations in Christ. So vehement was this party that they refused to permit the pope to perform divine service in the church of St. Mary, until he had publicly declared his condemnation of it. We have no other particulars relating to this pope, who died in the year 657, but he was commended by his contemporaries and successors for piety, mildness, humanity, and generosity. Moreri. Bower.

**EUGENIUS II.** pope, was a Roman by birth, and

from being archpriest of St. Sabina, was made bishop of Rome in the year 824. This election was opposed by the people, who made choice of a different person for pope. The double election excited considerable disturbances at Rome, which occasioned the interference of Lewis the Debonnaire, who decided for Eugenius, and confirmed him in his high office. The monarch took this opportunity of reviving several ancient customs and laws, declaratory of the dependence of the bishops of Rome on the imperial power, and determining the limits of the submission and obedience which were paid to them. Eugenius, to secure his own power, took the oath of fidelity to Lewis and his son Lotharius, in which was included their solemn engagement that no future pope should be consecrated with their consent, but in the presence of the emperor's deputy, and after the exaction of a similar oath to what was at that time administered. During the pontificate of Eugenius, a council was assembled in France under the auspices of Lewis and the Greek emperors Michael and his son Theophilus, to examine the doctrine of the Greek church, in relation to images. This was in the year 825, and at the conclusion of the council the bishops wrote a letter to Lewis, giving sentence against both parties, *viz.* the churches of Constantinople and Rome; the former for breaking images, whence they were denominated "Iconoclastæ," and the latter for worshipping them, whence they obtained the title of "Iconolatæ," declaring at the same time that it was a far greater crime to worship than to break images. The emperor was also exhorted by the council to interfere with the pope, and to intreat him to abolish the superstitious worship of images, which was the cause of much offence to all good men. Lewis wrote to the pope, and deputed two bishops to reason with him on the subject, but to little or no purpose; he continued not only to promote, but to justify the practice of image worship. In the following year Eugenius held a council at Rome, in which a number of decrees were passed, intended to reform the state of ecclesiastical discipline, and to encourage the progress of literature both sacred and profane, but he died in the year 827, before he could carry his plans into effect. He was highly spoken of by Catholic writers, and applauded for his humility, his beneficence, and the humane policy of his government. He is represented as excelling in mental and corporeal endowments. As a writer, two of his epistles, and eleven of his decrees, are extant in the seventh volume of the "Collectio Conciliorum." It has been reported, and not greatly to the credit of Eugenius, that he was the institutor of the ordeal by cold water. See ORDEAL. Moreri. Bower.

**EUGENIUS III.** pope, so called upon his elevation to the popedom, from his usual name Bernard, was a native of Pifa, and a disciple of St. Bernard. On the death of Lucius II. in the year 1145, Bernard was unanimously fixed on by the cardinals as the new pope, and was enthroned with the usual ceremony under the title of Eugenius III. The people, who had been long struggling to wrest from the popes the sovereignty which they had acquired over them in temporal matters, would not suffer Eugenius to be consecrated, unless he resigned all pretensions to dominion, otherwise than as connected with his spiritual rank, and would be contented with the revenue to be derived from tithes, and the voluntary contributions of the faithful. Unwilling to make these concessions, he privately withdrew to the Benedictine monastery of Farfa in Sabina, whither he was followed by the cardinals, and consecrated. Not daring to return to Rome, he removed from Farfa to Viterbo, where he continued for some months. During his abode there ambassadors arrived from the Crusaders in the East, to im-  
plore

## EUGENIUS.

plore assistance from the pope and the western princes against the Turks, who had gained some important advantages over them. Eugenius supplicated the assistance of Lewis VII. king of France, strongly urging him to march in person to the relief of the Christians in the Holy Land, and conferring on those who should attend him the privileges which his predecessors had granted to such as engaged in the holy war. Lewis embarked, and Eugenius now took measures to reduce the Romans to submission, which he effected in a short time, and forced them to acknowledge him as their temporal as well as spiritual lord. His triumph was of no long duration, for an insurrection obliged him to seek for personal safety in flight. He went to Treves, where he held a council in the year 1146. In the following year he was respectfully entertained at Paris by the king; and here he was allowed to hold a council, in which William, archbishop of York, was deposed from his dignity. From Paris he went to Rheims, where, in 1148, he held that council before which the fanatic Eon was examined. See EON. He next returned to Italy, and, with the assistance of the king of Sicily, once more subdued the people of Rome, in the year 1149. Shortly after this he was obliged to retire into Campania, where he remained till the year 1152. During this period he was not inactive, but sent a legate into Ireland, by whom he established the four archbishoprics in that kingdom. He was now permitted to return to Rome, where he lived in peace till his death in 1153. His virtues have been highly commended by his contemporaries. By some writers his chief merit arises from his zeal and sufferings in promoting the interests of the holy see, and in combating the errors of heretics: by more modern historians his memory has been held in abhorrence on account of the active part which he took in promoting the Crusades, by which great calamities overwhelmed Europe and the eastern world. Moreri. Bower. See CROSSADE.

EUGENIUS IV. pope, was a native of Venice, and of plebeian rank, though descended from an ancient family. His original name was Gabriel Condelmerio, and while he was very young he accompanied a nephew of pope Gregory XII. to Rome, where he took the Celestine habit. He was afterwards made treasurer to the pope himself, and then bishop of Sienna. In 1408 he was advanced to the office of cardinal presbyter of St. Clement. While Martin V. was pope he was sent delegate into the Marche of Ancona, and afterwards to Bologna, and performed the duties reposed in him with great ability and reputation. On the death of Martin in 1431, he was elected to the papal see, when he assumed the name of Eugenius IV. Immediately upon his elevation he involved himself, and the city of Rome, in the most alarming difficulties, by attempting to seize upon treasures said to have been left by his predecessors; and no sooner was he extricated from the dangers resulting from this conduct, than he drew upon himself fresh troubles with the council of Basil, which he determined to dissolve on account of their conciliating measures with the Hussites of Bohemia. His legate, cardinal Cæsarini, whom he empowered to act on the occasion, a man of much discretion, forewarned him of the troubles he was likely to bring on himself by the act. Eugenius had, however, made up his mind, and in 1431 issued his bull, declaring the council of Basil to be dissolved, and appointing another to be convened in eighteen months at Bologna. The emperor urged the pontiff to revoke his decree, setting forth in strong and very pressing terms the evils into which he would otherwise plunge the Christian world; and he added that he was sure the assembled bishops would not submit to be disappointed

of the object of their meeting, and that he, as protector of the church, was bound to afford them his support. Eugenius was immovable, and the council were alike determined to set his power at defiance. After confirming the decrees of the council of Constance, which declared the papal power to be subordinate to that of a general council, and bound by its statutes and mandates, they voted that no power on earth could dissolve them without their consent, and that none should withdraw from them without their leave; and they went so far as to summon the pope to appear in person before them within a limited time, or to send legates with full authority to act in his name. The firmness of the council, after much altercation, brought the pope to submission, and in the year 1433 he issued a bull, declaring null and void whatever had been done by him, or in his name, in derogation of the council-general of Basil. In the same year Eugenius received the emperor Sigismund at Rome with great magnificence, and crowned him there. Shortly after this he was attacked by Philip duke of Milan, who laid waste the territory of Rome, and when the inhabitants laid their complaints before the pope, he referred them to the cardinal his nephew, who, regardless of every thing that did not contribute to his own ease and pleasure, treated their sufferings with neglect and contempt. Enraged at this behaviour they took up arms, and produced a temporary revolution at Rome. It was with the utmost difficulty that Eugenius escaped from their fury, and took refuge at Florence; a reconciliation was effected, which was farther confirmed through the mediation of the council of Basil, who dispatched some of their body to offer friendly advice on the occasion. In 1437 fresh dissensions arose between the council and the pope, which terminated in their final rupture, and a new council was appointed to meet at Ferrara, whose first act was to declare the congregation of Basil an unlawful assembly, and themselves the only oecumenical council lawfully assembled, and they ordered all bishops who still remained at Basil to withdraw from that city within thirty days, on pain of excommunication, and the forfeiture of their dignities and benefices. The council of Basil, on the other hand, passed a decree or sentence of suspension against Eugenius from papal jurisdiction, forbidding all ecclesiastics, on pain of excommunication, to obey him. Early in the year 1439, a contagious disorder breaking out at Ferrara, the pope translated the council to Florence, where a pretended union was effected between the Greek and Latin churches, which, being violently opposed at Constantinople, was rendered null and void. In the mean time the council of Basil, after declaring the superiority of councils over the pope to be an article of the Catholic faith, proceeded to depose Eugenius from the papacy, as disobedient to the commands of the church, a contemner of the canons, a disturber of the unity of the church, and an obstinate heretic; and they dispatched nuncios to the different courts of the Christian princes to acquaint them with the measures which had been adopted. Eugenius thundered out his excommunications against the fathers at Basil, but they held his decrees in derision, and raised to the papal throne Amadeus, duke of Savoy, who assumed the name of Felix V. The rival popes and rival councils anathematized each other, laying claim to the true apostolic powers. Eugenius was supported by France, Italy, Spain, Portugal, Hungary, and England, but Felix was defended by the people of Savoy, by the Swiss, and by the dukes of Bavaria and Austria. The German princes chose to preserve a neutrality till the year 1447, when they declared for Eugenius, determining that he was the only true vicar of Christ upon earth. In the midst of the public rejoicings on this occasion, he died in his

his sixty-fourth year. His character as a pope is easily gathered from what has been said; he was ambitious, intriguing, and a decided enemy to reform. In his last illness he is said to have been painfully affected with reflections on his past life; "Oh Gabriel," exclaimed the dying pontiff, "how much better had it been for thy soul's safety, hadst thou never been promoted to the dignity of cardinal or pope!" He was a patron of literature and learned men, though he had no pretensions to learning himself; his epistles and bulls are to be found in volumes xii. and xiii. of the "Collectio Conciliorum." He was a handsome man, of a venerable aspect, and always looked downwards when he appeared in public. He was frugal and temperate in his own person, but was liberal and hospitable; and at his table there was a princely magnificence. In this reign the cardinals began to indulge in the sports of the field, and to abandon themselves to all kinds of luxury. Bayle. Moreri. Bower.

EUGENIUS, Catholic bishop of Carthage, was raised to that situation in the year 481, at the request of the emperor Zeno, who had entered into a treaty of peace with Hunneric, at that time the reigning monarch. In the year 483, he was summoned, with the other Catholic bishops, by the king, to Carthage, to maintain a public debate in defence of their principles against the Arian bishops, whom he patronized. Eugenius undertook to draw up a treatise, explanatory of the Catholic faith, which was approved by all the bishops of his party, and presented to Hunneric, and he offered to defend the principles contained in it by an appeal to the sacred writings, as well as to the sentiments of the fathers. He also delivered a petition to that prince, in the form of an apology, the design of which was, to obtain peace for the Catholics. It was, however, of no avail; the bishops of that party were all sentenced to banishment, and Eugenius was sent into exile, amidst the dreary deserts of Tripoli. In the following year Hunneric died, and Eugenius was permitted to return to Carthage, but was again banished, on the accession of Thrasamund, and sent into Gaul. He died at Albi, in the year 505. His principal works are, "Expositio fidei Catholicæ," "Apologeticus pro fide;" "Altercatio cum Arianis;" and a letter to his people, exhorting them to constancy in the orthodox faith. Moreri.

EUGENIUS, bishop of Toledo, in the seventh century, was attached to the monastic life, but compelled, by order of the prince, to accept of the episcopal dignity in the year 646. He filled that see several years, and made a figure at the councils of Toledo, which were held in the years 653, 655, 656. He was author of a treatise "On the Trinity," and two books on miscellaneous subjects. He revised and improved Dracontius's work on the creation of the world, which was published at Paris, together with his "Opuscula," in the year 1619. Moreri.

EUGHTGUR, in *Geography*, a town of Hindoostan, in the circar of Kitchwara; 15 miles E. of Ougein.

EUGIA, in *Ancient Geography*, a small country of the Peloponnesus, in Arcadia.

EUGMO, in *Geography*, a small island on the east side of the gulf of Bothnia. N. lat. 63° 49'. W. long. 22° 42'.

EUGUBIO. See GUBBIO.

EUHYDRIUM, in *Ancient Geography*, a town of Greece, in Thessaly, according to Livy.

EVIAN, in *Geography*, a town of France, in the department of the Lemane, on the coast of the lake of Geneva, containing two parishes and two convents. The place includes 1502, and the canton 12,911 inhabitants, on a territory of 280 kilometres, and in 19 communes.

VOL. XIII.

Near Evian are some mineral waters, which render it in summer a place of resort. It is situated 23 miles N. E. from Geneva. N. lat. 46° 25'. E. long. 6° 24'.

EVICTION, from *evincere*, *I overcome*, in *Law*, signifies a recovery of lands or tenements by law.

EVIDENCE, a quality in things whereby they become visible and apparent to the eyes, either of the body or the mind.

The schoolmen distinguish evidence into *formal* and *objective*. The former is the act of the intellect, considered as clear and distinct; the latter consists in the clearness and perspicuity of the object; or it is the object itself so constituted as that it may be clearly and distinctly known.

Others divide evidence into *moral*, *physical*, and *metaphysical*. A thing is said to be *morally evident*, so far as we have a distinct notion or knowledge thereof, by unexceptionable witnesses; *physically*, so far as natural sense and reason, pointing out any thing, convince us thereof; *metaphysically*, when we enter fully and clearly into the essence of any thing.

Evidence is the essential and infallible character or criterion of truth, and is that in effect which with us constitutes truth.

If evidence should be found in propositions that are false, we should be compelled into error, since the assent we give to evidence is necessary: whence would follow this impious position, that God who made us is the author of our errors, as he has constituted us so as to put us under a necessity of falling into them.

It may be added that as we necessarily love truth and hate error, it seems inconsistent with the nature of a beneficent being to form us with a love of what we could not obtain, or not know whether we did obtain it or not; besides, that if we should err in things that are evident, as well as in those that are not so, we should sometimes find contradictions in evident propositions, as we commonly do in things that are obscure.

Evidence, therefore, must be allowed the mark of truth; and those things must be allowed true which carry with them such a degree of evidence as obliges us to assent to them. Whatever we see evidently agreeable to things whereof we speak, that we must acknowledge to be true.

The Epicureans allow of no other evidence but that of sense, or that arising from sense, it being a fundamental principle with them, that sense is the first and primary criterion of all truth. By evidence of sense, they mean that species or image exhibited by the sense or phantasy; which, when all impediments to a just judging, as distance, motion, medium, &c. are removed, cannot be contradicted or gainsaid; wherefore, the question being put, whether or not a thing be such as it appears; the answer is not to be given, till it has been tried and examined in all the ways, and by all the senses, of which it can be an object. See ERROR.

There are certainly other superior and less fallible sources or grounds of evidence than sense: such is that inward consciousness by which we learn what belongs to the mind, or that which Mr. Locke calls reflection; of which such are intelligence, intuition, and common sense, principally relating to those abstracted, or other propositions that carry their own evidence with them, and admit no doubt about them; whence we derive our assent to propositions called axioms and maxims: such is also reasoning, whereby we infer one truth from others by natural and just methods of argument, whence results science: such is likewise the testimony of others, on which we found the evidence of FAITH (see also TESTIMONY): to which we may also add

## EVIDENCE.

inspiration, or that impresson made on the mind by God himself, which gives a convincing and indubitable evidence of the truth of any proposition, and attested to others, either by prophecy or miracles. Watts's Logic, part ii. chap. ii. § 9.

By thus considering the various sources whence our perception and belief of any truth are derived, we may be led to distinguish evidence into intuitive and deductive, and that founded on testimony. Intuitive evidence comprehends that of pure intellection, of consciousness, and of common sense, under the last of which that of memory is included. (See INTUITIVE.) Deductive evidence is divided into scientific and moral; the latter of which includes those kinds of evidence that are deduced from experience, analogy, and testimony, to which may be added a mixed species, derived from the calculation of chances. (See DEDUCTIVE.) See also each of the above-mentioned subjects. See Campbell's Phil. of Rhet. book i. chap. 5.

The evidences of the Christian religion are distinguished into two kinds, the direct and collateral: the direct evidences are external and internal; the external are miracles and prophecy; the internal evidence is deduced from its excellence, considered in reference to the main and principal end of Christianity. Whatever does not either belong to its excellence considered in this light, or fall under the head of miracles wrought on purpose to attest it, or of prophecies fulfilled, and yet affords a proof or any real presumption of its truth and divinity, is a collateral evidence for it. All the collateral evidences of the truth of Christianity are in one sense internal evidences, because they all arise from some particulars in the nature of this religion, from some circumstances which have attended its reception, or sprung from it, or from some remarkable facts connected with it, and related in the gospel history. Of this kind is the argument deduced from its great efficacy at its first appearance, in banishing polytheism, idolatry, superstition, and the arts of magic; in softening the rigour of despotism, introducing moderation into government, excluding many inconvenient civil laws once generally prevalent, giving rise to others of a very happy tendency, resisting the laws of war, humanizing the manners, and improving the customs of nations, and reforming the temper and conduct of those who embraced it.

Another class of collateral arguments for the truth of the Christian religion, arises from particulars in its nature or effects produced by it, or from facts in the Gospel history, which cannot be at all accounted for but on the supposition of a Divine original; or which are, at least, most naturally explicable on that supposition. To this class may be referred those presumptive arguments deduced from the character of Jesus, so exalted, and yet so uniformly supported; the nature of his last discourses with his disciples; the character of some of his apostles; that of Judas the traitor; the controversies among Christians in the apostolic age; and the method used by Christ and his apostles, of referring their claims to the impartial inquiries of men. Other collateral arguments have an affinity to the external evidences of Christianity: such are those derived from the miraculous conversion of the apostle Paul and his subsequent conduct; from the character of the man of sin foretold by Paul; from the quick and extensive propagation of the Gospel; from the continuance and present state of the nation of the Jews. Some of these arguments have an immediate relation to the proof of Christianity from prophecies; others are related to the proof from miracles. Other arguments have an equal relation to the internal and external evidence of Christianity; such

is that deduced from the manner in which Christ and his apostles proposed the evidences of their mission, and the advantage they have gained in consequence of the opposition and scrutiny of unbelievers. See on this subject Lord Lyttelton's Observations on the Conversion and Apostleship of St. Paul, Duchal's Presumptive Arguments for the Truth of the Christian Religion, and Gerrard's Dissertation on the genius and evidences of Christianity.

EVIDENCE, in Law, is any proof, whether by testimony of men on oath, or by writings and records; the former called *parol evidence*, that is, by word of mouth, and the latter *written evidence*.

It is thus called, because the point in issue is hereby made evident to the jury. Evidence in the trial by jury includes not only that which is given in proof, but that which the jury may receive by their own private knowledge; for an account of which see the sequel of this article.

With regard to parol evidence, or witnesses, we may observe in general, that all witnesses, whatever be their religion or country, that have the use of their reason, are to be received and examined, except such as are *infamous*, or such as are *interested* in the event of the cause. All others are competent witnesses; though the jury from other circumstances will judge of their credibility. Infamous persons are such as may be challenged as jurors, *propter delictum*; and, therefore, never shall be admitted to give evidence to inform that jury, with whom they were too scandalous to associate. Interested witnesses may be examined upon a *voir dire*, if suspected to be secretly concerned in the event; or their interest may be proved in court. A party interested in a suit, or a wife for or against her husband, a husband against his wife, except in cases of treason, an alien infidel, persons *non sana memorie*, those that are attainted of conspiracy, or in a *præmunire* upon stat. 5 Eliz. cap. 1. popish recusants convicted on stat. 3 Jac. I. cap. 5. (See contra 1 Hawk. P. C. c. 12. § 6.) persons convicted of felony, perjury, &c. those who by judgment have stood on the pillory, or been whipped, whilst the judgment is in force, are disabled from giving evidence: but kinsmen, though ever so near, tenants, servants, maisters, attornies for their clients, but not against them, because they are obliged to keep their secrets, one of the jurors upon trial, and all others that are not infamous, who want not understanding, or are no parties in interest, may give evidence in a cause, though the credit of servants is left to the jury. (2 Rol. Abr. 685. 1 Vent. 243.) If after a man hath stood in the pillory, &c. he be pardoned, he may be an evidence; and though judgment of the pillory infers infamy at common law, by the civil and canon law it imports no infamy, unless the cause for which the person was convicted was infamous; and, therefore, such may be a good witness to a will, if not convicted of any infamous act. (3 Lev. 426, 427.) It has been held, that it is not standing in the pillory which disables a person for giving evidence; but standing there upon a judgment for an infamous crime, as forgery, &c. If for a libel, a man may be a witness. (5 Mod. 74. 3 Nels. Abr. 557.) Persons excommunicated cannot be witnesses; but persons outlawed may be witnesses, because the outlawry has no influence on their credibility. (Bull. N. P. 292, 3.) A man convicted of felony, and afterwards pardoned, may be a good evidence. (Raym. 369.) Burning in the hand is said to restore a person to his credit. (Ibid. 330.) A person condemned to be hanged for burglary, but having a pardon for transportation, hath been allowed to be a good evidence. (5 Mod. 108.) One outlawed for treason and pardoned may be an evidence. (State Trials, vol. iii. 515.) Persons acquitted, or guilty of the same

## EVIDENCE.

same crime, while they remain unconvicted, may be evidence against their fellows. (Kel. 17.) Although no evidence ought to be given of what an accomplice hath said, who is not in the same indictment; (State Trials, vol. ii. 414.) an informer may be a witness, though he is to have part of the forfeiture, where no other witnesses can be had. (Wood's Instit. 598.) If an action is brought against many persons for taking of goods, one of them may be admitted as an evidence against the rest. (Comberb. 367. 1 Mod. 282.) In criminal cases, as of robbery on the high way, in action against the hundred; in rapes of women, or where a woman is married by force, &c. a man or a woman may be an evidence in their own cause. (1 Vent. 243.) And in private enormous cheats, a person may give evidence in his own cause, where nobody else can be a witness of the circumstances of the fact but he that suffers. (1 Salk. 286.) Upon an information on the statute against usury, he that borrows the money, after he hath paid it, may be an evidence, but not before. (Raym. 190.) Although an alien infidel may not be an evidence, a Jew may, and be sworn on the Old Testament. (1 Inst. 6.) A quaker shall not be an evidence in any criminal cause unless he will take an oath: though on other occasions his affirmation shall be accepted instead of an oath. Stat. 7 and 8 W. III. c. 34. See QUAKER.

The oath of a Gentoo, sworn according to the circumstances of his religion, has been admitted in a civil matter. (1 Atk. 21.) And by Willes C. J. an infidel in general is an admissible witness, for the term does not imply that he is an atheist; but whenever it appears that a witness hath no idea of a God or religion, he shall not be permitted to give his testimony. (1 Atk. 40. 45.) When persons that are competent witnesses are served with a writ of *subpoena ad testificandum*, they are bound to appear at the trial on pain of 10*l.* to be forfeited to the king, to which the stat. 5 Eliz. cap. 9. has added a penalty of 10*l.* to the party aggrieved, and damages equivalent to the loss sustained by want of their evidence: but no witness, unless his reasonable expences be tendered him, is bound to appear at all; nor if he appears, is he bound to give evidence till such charges are actually paid him, except he resides within the bills of mortality, and is summoned to give evidence within the same. In a criminal cause, if a witness refuse to appear, and give evidence, being served with process, the court will put off the trial, and grant attachment against him; and as refusing to give evidence is a great contempt, the party may be committed and fined. (1 Salk. 278.) Preventing evidence to be given against a criminal is punishable by fine and imprisonment; and persons dissuading a witness from giving evidence, &c., and jurors or others, disclosing evidence given, are likewise offences punished in the same manner. (2 Hawk. P. C. c. 22.) Members of either house of parliament may be witnesses on impeachments. (State Trials, vol. ii. 612.) A person who hath a legacy in a will, is not a good witness to prove the will; but if he release his legacy, he may be a good evidence. (Skin. 704.) Thus also, a person who claims any benefit by a deed, may not be an evidence to prove that deed; and a person concerned in the same title of land in question will not be admitted as evidence. (Ibid. 705.) If a legatee is permitted to be sworn and examined, the counsel cannot afterwards except against his evidence. (1 Lord Raym. 730.) To obviate all difficulties, it is enacted by stat. 25 Geo. II. c. 6. that any devise to a person being witness to any will or codicil shall be void, and such person shall be admitted as a witness; and that any creditor attesting a will or codicil, by which his debt is charged upon land, shall be admitted

as a witness to the execution, notwithstanding such charge: the credit of every such witness being left to the consideration of the court and jury. The son of a legatee is no witness to a will in the spiritual court; but it is held he may be a good evidence to prove a nuncupative will, within the intent of the statute of frauds. (1 Lord Raym. 85.) See WILL.

One credible witness is sufficient evidence to a jury of any single fact in all civil actions, though the concurrence of two or more corroborates the proof; but in cases of high-treason, petit-treason, and misprision of treason, by statutes 1 Edw. VI. cap. 12. 5 and 6 Edw. VI. cap. 11. and 1 and 2 Ph. and Mar. cap. 10. two lawful witnesses are required to convict a prisoner, except in cases of coining and counterfeiting the seals, or unless the party shall willingly and without violence confess the same: and by stat. 7 W. III. cap. 3. the confession of the prisoner must be in open court; and both witnesses must be to the same overt-act of treason, or one to one overt-act, and the other to another overt-act of the same species of treason. Baron Montequieu, indeed, lays it down for a rule, Spirit of Laws, book xii. chap. 3. that those laws which condemn a man to death in any case, on the deposition of a single witness, are fatal to liberty.

All evidence is to be given in open court, in the presence of the parties, their attorneys, the counsel and all bystanders, and before the judge and jury: many advantages attend this way of giving testimony, *ore tenus*, a method familiar among the ancient Romans, as may be collected from Quintilian, Inst. Orat. lib. v. cap. 7. and it was continued as low as the time of Adrian; but the civil law, as it is now modelled, rejects all public examination of witnesses.

No witness is bound to give any answer by which he confesses or accuses himself of any crime. The court in criminal cases is to examine the witnesses, and not the prisoner or prosecutors. A witness shall not be permitted to read his evidence, but he may look at his notes to refresh his memory. A witness may not recite his evidence to the jury, after having gone from the bar, and he hath given his evidence in court; if he does, the verdict may be set aside. (Cro. Eliz. 159.) One that is to be an evidence at a trial, ought not to be examined before the trial, but by the consent of both parties, and a rule of court for that purpose. No evidence ought to be produced against a man, in a trial for his life, but what is given in his presence. State Trials.

Positive proof is always required whenever the nature of the case possibly admits of it.

Sometimes violent presumption will be admitted for evidence without witnesses; as where a person is run through the body in a house, and one is seen to come out of the house with a bloody sword, &c. but on this the court ought not to judge hastily, 1 Inst. 6. 673; and though presumptive and circumstantial evidence may be sufficient in felony, it is not so in treason. State Trials.

Though all presumptive evidence of felony should be admitted cautiously, for the law holds that it is better that ten guilty persons escape, than that one innocent suffer. (See PRESUMPTION.) Sir Matthew Hale lays down two rules, most prudent and necessary to be observed. 1. Never to convict a man for stealing the goods of a person unknown, merely because he will give no account how he came by them, unless an actual felony of such goods be proved: and, 2. Never to convict any person of murder or manslaughter, till at least the body be found dead; on account of two instances, which he mentions, where persons were executed for the murder of others, who were then alive, but missing. 2 Hal. P. C. 200.

Evidence by writings and records, is where acts of parliament, statutes, judgments, fines, and recoveries, proceedings of court, and deeds, &c. are admitted as evidence. The printed statute-book is good evidence upon a general act of parliament, which need not be pleaded; but in the case of a private act, it is otherwise; for there it must be pleaded and examined by the records of parliament before it can be admitted in evidence. Records and enrolments prove themselves; and a copy of a record or enrolment, sworn to, may be given as an evidence. (Co. Litt. 119. 262.) A record of an inferior court has been rejected in evidence; and the proceedings in county-courts, courts-baron, &c. may be denied, and then tried by a jury. But court-rolls of a court-baron, when shewn, are good evidence; and, in many cases, copies of the court-rolls are allowed as evidence. An ancient deed of thirty years standing proves itself; but modern deeds, and other writings, must be attested and verified by parol evidence of witnesses. The counterpart of a deed is no evidence, when the original is in being, and can be procured; though it may be, when the original cannot be procured. (Co. Litt. 225. 10 Rep. 92.) The counterpart of an ancient deed hath been admitted as evidence. (Mod. Caf. 225.) In case of a fine, a counterpart is good evidence of itself. (1 Salk. 287.) Although a witness swear to the hand and contents of a letter, if he never saw the party write, it will not be good evidence. If all the witnesses to a deed are dead, continual and quiet possession is presumptive evidence of the truth of it; yet it may receive farther credit by comparison of hands and seals. (Wood's Inst. 599.) When witnesses to deeds are dead, their hand-writing must be proved. (2 Inst. 118.) If one of several witnesses survive, a subpoena must be taken out against the living witness, and strict inquiry made after him, and affidavit made that he cannot be found, before the hand-writing of the deceased witnesses is to be proved. (1 Litt. 556.) And a shop-book may not be given in evidence for goods sold, &c. by 7 Jac. I. cap. 12. after one year, before the action brought, except there be a bill, &c. for the debt; unless between merchant and merchant in the usual intercourse of trade. In order to make books evidences, if the servant who was accustomed to make entries in it be dead, his hand must be proved; and this, when accompanied with other collateral proofs of fairness and regularity, is the best evidence that can then be produced. In debt, a release may be given in evidence; so may any matters of fact, tampering with witnesses, or fraud.

In order to prove a lease for years, nothing shall be admitted but the very deed of lease itself, if in being; but if that be positively proved to be burnt or destroyed, then an attested copy may be produced, or parol evidence given of its contents. No evidence of a discourse with another will be admitted, but the man himself must be produced: yet in some cases, as in proof of any general customs or matters of common tradition or repute, the courts admit of *hearsay* evidence, or an account of what deceased persons have declared in their life-time; but such evidence will not be received of any particular facts. The probate of a will, when it concerns merely personal estate, may be given in evidence; but where title of lands is claimed under a will, the original will must be shewn, not the probate, though if the will be proved in the Chancery, copies of the proceedings there will be evidence. (2 Rol. Abr. 687. Trials per pais, 234. 1 Salk. 286. Raym. 335.) In some cases the ledger-book of the ecclesiastical court in which the will is entered is sufficient evidence, being a roll or record of the court. (Bull. N. P. 245, 6.) Depositions of witnesses in Chancery between the same parties may be given as evidence at law, if

the witnesses are dead, and the bill and answer proved. Depositions before a coroner are admitted as evidence, the witnesses being dead, or gone beyond sea. (1 Lev. 180. 2 Nelf. Abr. 760.) The confession of a prisoner before a magistrate, &c. may be given in evidence against him. (See 2 Hawk. P. C. c. 46.) See Baron Gilbert's Treatise of Evidence, or the Introduction to the Law of Nisi Prius, 4to. 1767.

From this treatise the following rules of evidence are extracted. 1. In general, the best evidence must be given that the nature of the thing will admit of. 2. No person interested in the question can be a witness. To this rule there are some exceptions; as, 1. A party interested may be admitted in a criminal prosecution in most instances. 2. He may be admitted for the sake of trade in the common usage of business, as porters, apprentices, &c. 3. Where no other evidence is reasonably to be expected. 4. Where he acquires his interest by his own act, after the party who calls him as a witness has a right to his evidence. 5. Where the possibility of interest is very remote. 3. The third general rule is that hearsay is no evidence. 4. In all cases where a general character or behaviour is put in issue, evidence of particular facts may be admitted; but not where it comes in collaterally. 5. In every issue the affirmative is to be proved. 6. No evidence need be given of what is agreed by the pleadings, &c. &c. See PLEADING.

Sir Thomas Smith restrains evidence to authentic writings of contracts, written, sealed, and delivered. De Rep. Ang. lib. ii.

EVIDENCE, *demurrer to*. See DEMURRER.

EVIDENCE, *exception to*. See EXCEPTION.

EVIL, MALUM, in *Ethics*, a privation or absence of some proper or necessary good, or of some measure or degree thereof.

Evil is either *natural* or *moral*; between which there is this relation, that moral evil produces natural.

EVIL, *moral*, is defined a deviation from right reason; a discernment of right from wrong, being given us as a guide of our actions; or it is the disagreement between the actions of a moral agent and the rule of those actions, whencesoever it is derived, and howsoever made known; and no action can be morally evil unless the agent be properly such, intelligent and free, and capable of distinguishing, choosing, and acting for himself. This the philosophers call *inhonestum*, and *turpe*, as staining the image of God, and fulying our original beauty; likewise *malum culpæ*.

EVIL, *natural*, is a want of something necessary to the *benefic*, or perfection of a thing, or to its answering all its purposes; such are defects of the body, blindness, lameness, hunger, diseases, death. This species is denominated *triste, injucundum, noxium, and malum pænæ*.

Good and evil, says a learned writer, are opposites, and arise from the relations which things have to each other: for since there are some things which profit, and others which prejudice one another; and since some things agree, and others disagree; we call the former good and the latter evil. Whatever, therefore, is incommodious or inconvenient to itself or any thing else; whatever becomes troublesome or frustrates any appetite implanted by God; whatever forces any person to do or suffer what he would not, that is *evil*. These inconveniences appear to be of three kinds: those of imperfection; those that are natural; and those that are moral. By the evil of imperfection we may understand the absence of those perfections or advantages which exist elsewhere, or in other beings; by natural evil, pains and uneasinesses, inconveniences and disappointments of appetites arising from natural motions; and by moral evils, vicious elections, that is, such as are hurtful to ourselves,

or others. This opinion is otherwise stated in the following manner: all evil is inconveniency, but some inconveniencies arise from the series of natural causes without our consent, and sometimes our knowledge; these we call natural evils; but others happen from the abuse of elections, when an undue choice occasions them; and in this case, besides the natural evil that arises from them, there is likewise an obligation on the person that makes the choice to answer for the hurt he has done by it. Now these choices that bring inconveniencies are called moral evils; and the difference between natural and moral evil is not their both bringing inconveniencies and injury to ourselves or others, for this constitutes the nature of their evil, but that the ill effects of the one proceed from the choice, those of the other from natural causes; and hence the author of that choice is answerable for the one, but nobody for the other. Moral evil, therefore, is natural evil, with choice superadded. See archbishop King's "Essay on the origin of Evil," by Law, vol. i. and ii. Sherlock, also, in his "Treatise on Judgment," p. 20, &c. distinguishes in a similar manner between moral and natural good and evil; the only difference between them, he says, is this, "that moral good and evil is in the will and choice, natural good and evil is in the nature of things; that which is good or hurtful to ourselves or others is naturally good or evil; to love, to choose, to do that which is good or hurtful to ourselves or others, is morally good or evil, or is the good or evil of our choice or actions. If you will but recollect yourselves, you will find that you have no other notion of good or evil but this; when you say such a man has done a very good or very evil action, what do you mean by it? Do you not mean, that he has done something very good or very hurtful to himself or others? When you hear that any man has done good or evil, is not the next question, what good or what hurt has he done? And do not you mean by this, natural good or evil? which is a plain evidence that you judge of the moral good or evil of actions by the natural good or evil which they do."

The ingenious author of the "Enquiry into the Origin of our Ideas of Beauty and Virtue," gives the following statement of the nature of moral good and evil, and of the difference between these and natural good and evil. Moral evil, according to this philosopher, denotes our idea of a quality apprehended in actions which excites aversion and dislike towards the actor, even from persons who receive no disadvantage thereby; as moral goodness denotes our idea of a contrary quality which procures approbation and love towards the actor, even in persons unconcerned in its natural tendency. This notion supposes an universally acknowledged difference of moral good and evil from natural. Moral good, we all know, procures love towards those we apprehend possessed of it; whereas natural good does not. How differently, for instance, are we affected towards those we suppose possessed of honesty, faith, generosity, &c. when we expect no benefit from those qualities, and those possessed of the natural goods, as houses, lands, gardens, health, strength, &c. So whatever quality we apprehend morally evil, raises our hatred towards the person in whom we observe it; as treachery, cruelty, ingratitude, &c. whereas we love and pity many exposed to natural evils, as pain, hunger, sickness, &c.

The origin of these different ideas of actions has greatly puzzled the moralists: some make self-interest, or self-love, the source of them all; we approve the virtue of others as it has some small tendency to our happiness, either from its own nature, or from this general consideration, that a conformity to nature and reason is in the general advantage-

ous to the whole, and to us in particular; and on the contrary, disapprove the vice of others, as tending at the long run to our particular detriment.

Others suppose an immediate natural evil in the actions called *vicious*, that is, that we are determined to perceive some deformity or displeasure in such actions, without reflecting on any disadvantage that may any way redound to us from the action; and that we have a secret sense of pleasure accompanying such of our own actions as are called *virtuous*, when we expect no farther advantage from them; but then they add, that we are excited to perform those actions, even as we pursue or purchase pictures, statues, landscapes, &c. from self-interest, to obtain the pleasure which accompanies the action.

But the author just mentioned maintains that some actions have to men an immediate goodness, and others an immediate evil, *i. e.* we perceive pleasure in some and pain in others, and are determined to love or hate the doers, without any view of natural advantage, without any view to future rewards or punishments, or even without any intention to obtain the sensible pleasure of the good, but from a very different principle, *viz.* an internal moral sense, or a natural determination of the mind to receive amiable or disagreeable ideas of actions, when they shall occur to our observation, antecedently to any opinion of advantage or loss to redound to ourselves from them, even as we are pleased with a regular form or an harmonious composition, without any knowledge of the mathematics, or seeing any advantage in that form or composition different from the immediate pleasure. But according to this account of Dr. Hutcheson, however plausible, moral good and evil signify nothing in the objects themselves, to which they are applied, any more than agreeable and harsh, sweet and bitter, &c. but only certain effects in us; and virtue is a mere affair of taste; whereas it seems to be much more just to conclude, that right and wrong, or good and evil, are real qualities of actions, and not merely of our minds; and that the power whereby we perceive these qualities is not any arbitrary sense but the understanding: or to suppose with another excellent writer, that moral good, considered as synonymous with virtue, denotes the doing good to mankind, in obedience to the will of God, and for the sake of everlasting happiness, and moral evil or vice, the contrary. Price's Original of our Ideas, &c. p. 13, and p. 59, &c. Paley's Principles of Moral and Political Philosophy, vol. i. p. 41. See farther under DEFORMITY, SENSE, GOOD, VIRTUE, and VICE.

The question concerning the origin of evil has very much perplexed philosophers and divines, both ancient and modern. Plato, for the solution of this question, maintained, that matter, from its nature, possesses a blind and refractory force, from which arises in it a propensity to disorder and deformity; and that this is the cause of all the imperfection which appears in the works of God, and the origin of evil. Matter, he conceives, resists the will of the supreme artificer, so that he cannot possibly execute his designs; and this is the cause of the mixture of good and evil, which is found in the material world. "It cannot be," says he, (Theæt. t. i. p. 176.) "that evil should be destroyed, for there must always be something contrary to good;" and again, "God wills, as far as it is possible, every thing good, and nothing evil." What is that property of matter which opposes the wise and benevolent intentions of the first intelligence, Plato has not clearly explained, but he speaks of it as *ἑτέροφρωνος ἐπιθυμία*, an innate propensity to disorder, (Phileb.) and says, "that before nature was adorned with its present beautiful forms, it was inclined to confusion and deformity, and that from this ha-

bitude arises all the evil which happens in the world." Plutarch supposes the Platonic notion to be, that there is in matter an unconscious irrational soul; and this supposition has been adopted by several modern writers. But the writings of Plato afford no evidence, that he conceived the imperfection of matter to arise from any cause distinct from its nature. Such a notion is incongruous with Plato's general system, and it is contrary to the doctrine of the Pythagorean school, to which he was probably indebted for his notions on this subject; for the philosophers of that sect held, that motion is the effect of a power essential to matter. Some of the Stoics adopted the notion of the Platonists concerning the origin of evil, and ascribed it to the defective nature of matter, which it is not in the power of the great artificer to change; asserting, that imperfections appear in the world, not through any defect of skill in its author, but because matter will not admit of the accomplishment of his designs. But it was perceived by others, that this hypothesis was inconsistent with the fundamental doctrine of the Stoics concerning nature. For since, according to this system, matter itself receives all its qualities from God, if its defects be the cause of evil, these defects must be ultimately ascribed to him. No other way of relieving this difficulty remained, but to have recourse to fate, and say, that evil was the necessary consequence of that eternal necessity, to which the great whole, comprehending both God and matter, is subject. Thus, when Chryssippus was asked, whether diseases were to be ascribed to divine Providence, he replied, that it was not the intention of nature that these things should happen; nor were they conformable to the will of the author of nature and parent of all good things; but that, in framing the world, some inconveniences had adhered, by necessary consequence, to his wise and useful plan. To others the question concerning the origin of evil appeared so intricate and difficult, that finding themselves unequal to the solution of it, they denied either that there is any God at all, or, at least, any author or governor of the world. The Epicureans belonged to this class; nor does Lucretius allege any other reason for denying the system of the world to be the production of a deity besides its being so very faulty. Others again judged it to be more rational to assign a double cause of visible effects than to assign no cause at all; as nothing, indeed, can be more absurd than to admit actions and effects without any agent and cause. These persons, perceiving a mixture of good and evil, and being persuaded that so many inconsistencies and disorders could not proceed from a good being, supposed the existence of a malevolent principle, or God, directly contrary to the good one; hence they derived corruption and death, diseases, griefs, mischiefs, frauds and villainies, whilst from the good being they deduced nothing but good. This opinion was held by many of the ancients; by the Persian magi, Manichæans, Paulicians, &c. &c. See these articles, and also ZORASTER. Absurd as this hypothesis was, it very long and generally prevailed, not only in the Heathen but in the Christian world; nor have the light and influence of Christianity yet availed to its total extermination, so that no trace or remnant of it remains. Those who wish to find a satisfactory refutation of it, may consult "King's Origin of Evil," vol. i. and the annexed notes of the editor.

The excellent Dr. Clarke, in his "Demonstration of the Being and Attributes of God," deduces from the possibility and real existence of human liberty an answer to the question, what is the cause and original of evil? "For liberty," he says, "implying a natural power of doing evil, as well as

good; and the imperfect nature of finite beings, making it possible for them to abuse this their liberty to an actual commission of evil; and it being necessary to the order and beauty of the whole, and for displaying the infinite wisdom of the Creator, that there should be different and various degrees of creatures, whereof, consequently, some must be *less perfect* than others; hence there necessarily arises a possibility of evil, notwithstanding that the Creator is infinitely good. In short thus: all that we call *evil*, is either an *evil of imperfection*, as the want of certain faculties and excellencies which other creatures have; or *natural evil*, as pain, death, and the like; or *moral evil*, as all kinds of *vice*; the first of these is not properly an evil. For every power, faculty, or perfection, which any creature enjoys, being the free gift of God, which he was no more obliged to bestow, than he was to confer being or existence itself; 'tis plain the want of any certain faculty or perfection in any kind of creatures, which never belonged to their nature, is no more an evil to them, than their never having been created or brought into being at all, could properly have been called an evil. The *second* kind of evil, which we call *natural evil*, is either a necessary consequence of the former; as *death*, to a creature on whose nature immortality was never conferred; and then 'tis no more properly an evil than the former; or else 'tis counterpoised, in the whole, with as great or greater good; as the *afflictions and sufferings of good men*; and then also it is not properly an evil; or else, lastly, 'tis a *punishment*; and then 'tis a necessary consequent of the *third* and last sort of evil, *viz. moral evil*. And this arises wholly from the abuse of *liberty*, which God gave to his creatures for other purposes, and which 'twas reasonable and fit to give them for the perfection and order of the whole creation: only they, contrary to God's intention and command, have abused what was necessary for the perfection of the whole, to the corruption and depravation of themselves. And thus all sorts of evils have entered into the world, without any diminution to the infinite goodness of the Creator and Governor thereof.

EVIL, or *King's Evil*, the appellation formerly given to *scrofula*, in consequence of the supposed power possessed by the kings of England and France of curing this disease by *touching* the sick.

The origin and first exercise of this royal faculty are not agreed upon by historians; those of France are disposed to maintain, that it was originally inherent in their kings, some asserting that St. Louis, others that king Robert, was the first who was thus gifted; but by most other writers it is assigned as an earlier prerogative of the English crown. Edward the Confessor is generally mentioned as the first possessor of this miraculous power: and it was disputed in the days of Malmsbury, who lived not long after his reign, whether this faculty were a peculiar reward from heaven for that king's sanctity, or hereditarily resident in the English crown. Polydore Virgil has noticed this gift to Saint Edward, and its continuance in the line of his successors; and Dr. Harpsfield, in his Ecclesiastical History of England, after describing the miracles of the Confessor, observes, "quam strumofos sanandi admirabilem dotem in posteros suos Anglorum reges, ad nostra usque tempora transfudisset perpetuasse, merito creditur." The practice was long continued, and seems to have reached its greatest height in the reign of Charles II. to whom multitudes flocked to receive the benefits of the royal touch; inasmuch, that after his restoration, he is said to have laid his hands upon more than six thousand persons in one year. His majesty was therefore obliged to make some restrictions with regard to the times of healing, and the number of patients. All persons were obliged to go to the king's surgeon, whose duty it was to examine

## E V I L.

examine their certificates from the minister and church-wardens of their parish, to determine whether they were proper objects, to give them tickets of admission to the royal presence, and to introduce every one to the king's sacred hand to be touched. The king usually gave public notice of the day of healing; in the winter the ceremony was always held at Whitehall; in the summer sometimes at Whitehall, and sometimes at Windsor.

The following curious paragraphs were made public in 1660.

"The kingdom having been for a long time troubled with the evil, by reason of his majesty's absence, great numbers have lately flocked for cure. His sacred majesty, on Monday last, touched 250 in the Banqueting house; among whom, when his majesty was delivering the gold, one shuffled himself in, out of an hope of profit, which had not been stroked, but his majesty quickly discovered him, saying, this man hath not yet been touched. His majesty hath for the future appointed every Friday for the cure, at which 200, and no more, are to be presented to him, who are first to repair to Mr. Knight, the king's surgeon, &c. Parliamentary Journal, July 2—9, 1660.

"Saturday being appointed by his majesty to touch such as were troubled with the evil, a great company of poor afflicted creatures were met together, many brought in chairs and flasks; and being appointed by his majesty to repair to the Banqueting-house, his majesty sat in a chair of state, where he stroked all that were brought to him, and then put about each of their necks a white ribbon, with an angel of gold on it. In this manner his majesty stroked above six hundred; and such was his princely patience and tenderness to the poor afflicted creatures, that though it took up a very long time, his majesty, who is never weary of well-doing, was pleased to make inquiry whether there were any more that had not yet been touched. After prayers were ended, the duke of Buckingham brought a towel, and the earl of Pembroke a basin and ewer, who, after they had made obeisance to his majesty, kneeled down till his majesty had washed." Mercurius Politicus, June 21—28, 1660.

An exact register was at that time kept of the number of cases that came for relief, and the whole amount is very great. From 1660 to 1664 inclusive, a period of five years, 23,601 persons were touched by Charles II.: and from May 1667 to May 1684, the number of persons touched amounted to 68,506; making all together 92,107. For the intervening years, 1665 and 1666, no register was made, the king having removed from the metropolis on account of the plague.

This superstitious practice was dropped by the present royal family, "who observed (says Hume) that it could no longer give amazement, even to the populace, and was attended with ridicule in the eyes of all men of understanding." Rapin indeed remarks, that "the late king William III. of glorious memory, was so persuaded he should do no injury to persons afflicted with this distemper, by not touching them, that he refrained from it all his reign." The practice continued in vogue in the reign of queen Anne; it is recorded of Dr. Johnson, that he was touched by that princess, but without effect.

It is extraordinary that this belief in the efficacy of the royal touch in the cure of this severe disease was by no means confined to the vulgar, nor to persons unacquainted with the nature and cure of diseases. Dr. Johnson's mother is said to have been instigated by the advice of a celebrated physician, sir John Floyer, to bring her son to London for the purpose of receiving the remedy. And Wiseman

and Browne, eminent surgeons of their day, and surgeons to the king (Charles II.) have given their strongest testimony in favour of the superiority of the royal remedy, over any which their art possessed. "I must needs profess," says Wiseman, "that what I write will do little more than shew the weakness of our ability, when compared with his majesty's, who cureth more in any one year, than all the chirurgeons of London have done in an age. However, that this attempt may not seem to want precedent, give me leave to tell you, that it is no more than the French kings' chirurgeons have done before me, or than old Mr. Clows did in queen Elizabeth's days, and all other general writers in chirurgery have done more or less." And he affirms that he had been "a frequent eye-witness of many cures performed by his majesty's touch alone, without any assistance of chirurgery; and those many of them such as had tired out the endeavours of able chirurgeons before they came thither."

The other surgeon royal just mentioned has left us the most circumstantial account of this royal healing, in a publication, entitled "Adeno-choiradologia; or, an Anatomick-Chirurgical Treatise of Glandules and Strumæ, or King's-evil-swellings, together with the Royal Gift of Healing, or Cure thereof, by Contact or Impolition of Hands, performed for above 640 years by our kings of England; continued with their admirable effects and miraculous events; and concluded with many wonderful examples of Cures by their sacred touch. All of which are succinctly described by John Browne, one of his Majesty's Chirurgeons in Ordinary, and Chirurgeon of his Majesty's Hospital, London, 1684." His offices evince that the author was a man of character, and his book is approved, as was the custom of his time, by the president and several fellows of the College of Physicians. Like Wiseman, he seems to have been a staunch loyalist, and a vehement defender of the divine right of kings; he detested all dissenters, and confidently asserts that the usurper, Cromwell, tried in vain to exercise this royal prerogative, "he having no more right to the healing power, than he had to the regal jurisdiction." The third part of the treatise of Browne, which is devoted to the history and nature of the royal gift, is entitled *Charisma Basilicon*. Besides an historical view of this prerogative, it contains rules for the meanest capacity to find out the disease, which were deemed expedient to prevent poor people from unnecessary journeys; and sixty admirable cures, performed with or without gold, are circumstantially detailed, as well as several cases of scrofulous tumours and sores, which disappeared on being touched with handkerchiefs dipped in the blood of Charles I.

Some shrewd suspicions had, indeed, been thrown out; that the piece of gold, given by the king on the occasion, was the most efficacious remedy employed; and the above mentioned writers are anxious to refute such a slander on the royal qualifications. The author of a late treatise tells the following story, which may, in some degree, account for the numbers registered at Whitehall. "An old man, who was witness in a cause, had by his evidence fixed the time of a fact, by queen Anne having been at Oxford, and touched him while a child, for the cure of the evil. When he had finished his evidence, the relator had an opportunity of asking him whether he was really cured. Upon which he answered, with a significant smile, that he believed himself never to have had a complaint, that deserved to be considered as the evil; but that his parents were poor, and had no objection to the bit of gold." See Wiseman's Chirurgical Treatises, book iv. chap. 1. Browne above cited. Edin. Med. and Surg. Journal, vol. iii. p. 185.

EULEPA, in *Ancient Geography*, a town of Cappadocia. Itin. Anton.

EULER, LEONARD, in *Biography*, a great mathematician, was born at Basil in the year 1707, where he was educated. He performed his academical tasks with so much rapidity, that he had a good portion of time left at his own command, which he consecrated to the study of the mathematics. In the pursuit of this kind of knowledge, he was assisted by John Bernouilli, who was regarded as one of the chief mathematicians of Europe, and whose distinguished attention and esteem he obtained, by his early proficiency and unwearied application. In 1723, M. Euler was admitted to the degree of M. A. on which occasion he obtained great applause by delivering a Latin discourse, wherein he drew a comparison between the philosophy of Newton and the Cartelian system. In compliance with his father's desire, he applied himself to theology and oriental literature, in which he made no inconsiderable progress, but his predominant bias still leading him to the mathematics, his father allowed him to follow the bent of his inclination. In the course of his studies under Bernouilli, he contracted an intimate friendship with his two sons, Nicholas and Daniel, which proved to be of the highest advantage to him in after life. Those two celebrated mathematicians having been invited to Petersburg, in the year 1725, by Catharine I. for carrying into execution the project of Peter the Great, for the establishment of an academy of science, promised Euler to use their endeavour to find him a situation in that city. By their advice he applied himself diligently to the study of natural knowledge, and attended the lectures of all the eminent professors of Basil. While engaged in these pursuits he composed a dissertation "On the nature and propagation of Sound;" and also an answer to a prize question, "Concerning the masting of Ships," which obtained the second prize. By this circumstance his attention was early drawn to the curious and important studies of naval architecture and navigation, which he contributed greatly to enrich in the subsequent periods of his life. He now joined his friends the Bernouillis at Petersburg, and was appointed with them a joint professor in the university of that city. In this situa-

tion his talents and genius were so far called into exercise as to entitle him to rank among the most eminent mathematicians. He contributed many memoirs to the academical collection, which excited a noble spirit of emulation between him and his two friends, unalloyed by the least mixture of envy or jealousy, and such as produced no alteration in their friendship. The integral calculus he carried to new degrees of perfection; invented the calculation of sines; simplified analytical operations, and in this way threw new light on all the branches of mathematical science. In 1730, M. Euler was appointed professor of natural philosophy; and, in 1733, he succeeded his friend Daniel Bernouilli, in the mathematical chair. In 1735, the academy proposed an intricate and important problem for solution, which Euler completed in three days, though it was supposed to be the labour of many months. The exertion on this occasion was so violent that it produced a fever which endangered his life, and deprived him of the use of one of his eyes. In the year 1740, the Academy of Sciences at Paris proposed for solution the important subject of "The flux and re-flux of the sea." To this Euler applied the force of his genius, and produced a memoir, which was allowed to be a master piece of analysis and geometry. He had, however, as competitors, Daniel Bernouilli, and our countryman, Colin Maclaurin, with whom he shared the prize. In 1741, Euler, at the express invitation of the king of Prussia, repaired to Berlin, where his industry and talents appeared to great advantage. He furnished many essays for the memoirs of the Prussian academy, without withholding his contributions from the academy of Peterburgh, which was now encouraged by the patronage and munificence of the empress Elizabeth. In 1742, he obtained a pension from the academy at Peterburgh, and in 1766, by permission of the king of Prussia, he returned to that city, to spend the remainder of his days; when the munificence of Catharine II. liberally rewarded him for the preference which he exhibited towards his Peterburgh connections. Shortly after his return he lost the sight of the other eye, yet in this deplorable situation he dictated to his servant, an unlettered youth, and who was entirely unacquainted with mathematical knowledge, his "Elements of Algebra," a work of high merit, and which has been translated into the English language. At this period he was elected one of the very few foreign members of the Academy of Sciences at Paris. After this he received from them the prize for his dissertations "Concerning the inequalities in the motions of the planets;" also two prizes for questions proposed relative to "A more perfect theory of the moon." He next reviewed his whole theory with the assistance of his son, and Messrs. Krafft and Lexell; and pursued his researches till he had constructed the new tables which appeared with the great work in 1772. "This work alone," says his biographer, "would be sufficient to render his name immortal, and when it is considered that it was completed after he was totally blind, and at a time in which he was embarrassed in his domestic circumstances by a dreadful fire, that had consumed great part of his substance, and forced him to quit the ruined house; it is impossible not to be struck with admiration and astonishment at the powers of his genius and memory, and the perseverance, fortitude, and tranquillity of mind which he must have possessed." Some time after this he underwent the operation of couching, which restored to him his sight; but either too eager to benefit by the organ, or by the negligence of his surgeon, he was a second time deprived of his sight, and the relapse was attended with much tormenting pain. Still he

he was active in the pursuit of science, and in the course of seven years transmitted to the academy of Petersburg seventy distinct memoirs, and left behind him two hundred more, which were afterwards revised and completed. In the beginning of September, 1783, he was seized with several attacks of a vertigo; these, however, did not prevent his calculating the motion of air-balloons, which then began to engage the attention of the philosophical world; but on the 7th of the same month, while he was amusing himself with his grand-children, an apoplectic fit terminated his illustrious career, at the age of 76. Besides being foreign member of the Royal Academy of Sciences at Paris, M. Euler was member of the Imperial Academy of Petersburg, ancient director of the Royal Academy of Berlin, and fellow of the Royal Society of London. His works were very numerous; his knowledge was not confined to his favourite studies of the mathematics and astronomy, of which he has secured to himself an imperishable fame. He had made much progress in medical, botanical, and chemical science. He also possessed, in a high degree, what is generally called erudition. He had read with attention and taste the most eminent Latin classics, and was familiarly acquainted with the civil and literary history of all ancient and modern nations. His uncommon memory seemed to retain every idea that was conveyed to it either from reading or from meditation. The *Æneid* of Virgil he could repeat from the beginning to the end, and point out to his hearers the first and last line of every page in the edition which he used. He enjoyed a vigorous constitution, and a surprising share of health, considering the intensity and ardour of his application. His manners were unaffected and pleasing, his temper lively and cheerful, and his conversation both instructive and entertaining. The evening of his days was calm and serene, sweetened in no small degree by the fame that follows genius, the universal esteem and respect that were due to his exemplary virtues, and the satisfaction which he received from the kind offices of friendship, and the endearments of domestic felicity.

This great geometrician had bestowed much meditation, early in life, on harmonics, or the philosophy of sound; for in 1739, at the age of 32, he published at Petersburg, in Latin, a work in 4to. under the title of "Tentamen novæ Theoriæ Musicæ ex certissimis harmoniæ principii dilucidè expositæ, auctore Leonardo Eulero." This work, being written in Latin, and requiring in the reader, besides that language, a knowledge in geometry, algebra, and fluxions, was little noticed by the public at large on its first appearance, and still less understood by musicians, for whose use it must have been chiefly intended. It, however, set mathematicians and men of science to work, and started many curious subjects of meditation to such as interested themselves in the study of harmonics.

But we do not very well see how the author could with propriety call his treatise an attempt at a *new* theory of music. The ratios were all known ever since the time of Euclid. Indeed he has followed the proportions which Zarlino tried to establish in his "Institutioni," which had been adopted by Des Cartes, Rameau, Tartini, &c.; and Des Cartes, and others after him, had accounted for the pleasure which we receive from concords, by the simplicity of the ratios between the sounds which form them. There is a plate, p. 35, representing, we thought, in a new and ingenious manner to the eye, the pulsations of two strings; the one fixed to a given tone, and the other tuned progressively to all the consonant intervals, which clearly shews the coincidences of vibration, upon the frequency of which the

degree of sweetness and perfection in concords depends. We believe, however, that this was done in the 17th century, but in a less elegant manner, by our countryman lord keeper North, in a quarto pamphlet of only twenty-five pages, intitled, "A Philosophical Essay of Musick directed to a Friend;" London, 1677.

In this little tract the vibrations of each consonance are represented to the eye, and the coincidences with the fixed tone, its base or principal, in the same manner as in the work of the great geometrician Euler, who has pushed ratios as far as our perception and appreciation can go, extending the whole compass of our musical system to eight octaves. See COMPASS.

The degrees of suavity in consonance from the simplicity of ratios and frequency of coincidence, had, we believe, been settled before the year 1739, when this treatise was published.

The following is a translation of the titles of the several chapters of this work. After a preface of twenty pages, Chap. I. treats of sound, and the auditory sense.

- II. Of the sweetness and principles of harmony.
- III. Of music in general.
- IV. Of concords.
- V. Of concords in succession.
- VI. Of a series of concords.
- VII. Of intervals, and their names.
- VIII. Of the genera of music.
- IX. Of the diatonic-chromatico genus.
- X. Of other more compounded genera.
- XI. Of the concords in the diatonic-chromatico genus.
- XII. Of the modes or keys and systems in the diatonic-chromatico genus.
- XIII. Of the ratio of composition in a given mode and system.
- XIV. Of the modes and systems in transposed keys.

In the 13th chap. on the laws of composition, and the possible combinations in any given mode, key, or system, some of these combinations employ every note in the scale, seemingly at once, which would be extremely offensive if heard together. The author probably means, that all these sounds may be heard successively in melody, provided they are in tune, and have a fundamental base.

Upon the whole, Euler seems not to have invented much in this treatise; and to have done little more than arrange and methodize former discoveries in a scientific and geometric manner. He may, indeed, not have known what antecedent writers had discovered before; and though not the first, yet to have imagined himself an inventor.

EULER'S *Logarithms*, or *Binary Logarithms*, are a species of artificial numbers contrived by M. Euler to facilitate the calculation and comparison of musical intervals, which they do, by representing each interval in *decimal parts* of the octave, which is 1 in this notation, the successive octaves or powers of 2 being represented by 2, 3, 4, &c. as in the following table, for the first 10 numbers, *viz.*

1 = 0.000000	6 = 2.584963
2 = 1.000000	7 = 2.807356
3 = 1.584963	8 = 3.000000
4 = 2.000000	9 = 3.169925
5 = 2.321928	10 = 3.321928

By help of the primes which compose musical ratios, and their binary logarithms in this table, the Euler's logarithm may be found, which answers to any interval: as the names of the several intervals occur, we shall give their binary logarithms.

**EULISIA**, in *Ancient Geography*, a country of Scythia, towards the Palus Mæotis.

**EULOGIUS**, in *Biography*, patriarch of Alexandria, was, at first, presbyter of the church of Antioch, and distinguished himself by his zeal for the Catholic doctrines in a letter which he wrote to Eutychius, patriarch of Constantinople, containing an exposition of the true faith. He was elevated to the see of Alexandria in the year 581, and became very active in rooting out heresy, not only by the allowable and fair weapons of reason and argument, but by expelling from their situation all ecclesiastics who were advocates for the doctrine of one nature in Christ. He lived in habits of intimacy with Gregory the Great, whose sentiments and disposition were congenial to his own. He died in 608. Of his works only fragments are remaining. Moreri.

**EULOGIUS**, elected archbishop of Toledo in the ninth century, was born at Cordova about the year 800. He was educated for the priesthood, and discharged the duties of that office with zeal and activity till the year 844, when he was driven into exile by the Saracens for his boldness in maintaining the principles of the Catholic faith. After much suffering he ventured to return to Cordova, where, in the year 850, he was thrown into prison on account of his religion. In the dungeon he employed himself in writing animating exhortations to the Christians, to support and console them under their persecution, for conscience sake, and to encourage them to undergo the severest trials rather than disgrace themselves by apostacy. He was afterwards liberated, and by his personal labours, as well as writings, persevered in fortifying his fellow Catholics against the arts and terrors of their enemies. As a reward for his exertions in this hazardous employment, he was chosen to fill the vacant see of Toledo; but he was put to death before he could receive the episcopal consecration. The accusation against him was the having converted a young Mahometan female to the Christian faith: he was beheaded in 859. He was author of "Memoriale Sanctorum, five Libri III. de Martyris Cordubensibus;" "Apologeticus pro Martyribus, &c.;" "Exhortatio ad Martyrium;" and some moral epistles. These were collected and printed with notes by Ambrosius Moralis in 1554, and again in a more correct form by Poncius Leo in 1574. Moreri.

**EULOGY, EULOGIA**, in *Church History*. When the Greeks have cut a loaf, or piece of bread, to consecrate it, they break the rest into little bits, and distribute it among the persons who have not yet communicated, or send it to persons that are absent; and these pieces of bread are what they call eulogies.

The word is Greek, *εὐλογία*, formed of *εὐ*, bene, well, and *λέγω*, dico, I say, speak; q. d. *benedictum, bless'd.*

The Latin church has had something like eulogies for a great many ages; and thence arose the use of their holy bread.

The name eulogy was likewise given to loaves or cakes brought to church by the faithful to have them blessed.

Lastly, the use of the term passed hence to mere presents made a person, without any benediction. See the Jesuit Gretser, in his *Treatise de Benedictionibus & Maledictionibus*, lib. ii. cap. 22. 24, &c. where he treats of eulogies thoroughly.

From a passage in Bollandus, on the Life of S. Melaine, cap. 4. it appears, that eulogies were not only of bread, but any kind of meat blessed and hallowed for that purpose. And that almost every body blessed and distributed eulogies; not only bishops and priests, but even hermits,

though laymen, made a practice of it. Women also would sometimes send eulogies.

The wine sent as a present was also held an eulogy. Bollandus remarks farther, that the eucharist itself was also called eulogy.

**EULOGY**, likewise, means an encomium on any person, on account of some virtue or good quality.

**EUMARIDES**, of *εὐμαρίς*, *easy*, among the *Ancients*, a kind of shoes common to men and women.

The eumarides were used for pomp and delicacy, being neat, and painted with various colours.

**EUME**, in *Geography*, a river of Spain, which runs into the sea near Corunna.

**EUMECES**, in the *Writings of the Ancient Naturalists*, the name of a dove which Pliney tells us resembled a flut, and was found in Bactria; the ancients had an idle opinion, that, if laid under the head, it occasioned true and prophetic dreams, foretelling to the person the more remarkable future events of his life. Hist. Nat. lib. xxxvii. cap. 10.

**EUMENES**, in *Biography*, a captain under Alexander the Great, was a native of Cardiopolis, in the Thracian Chersonese. His father was of a low station, but one in a condition to have entertained at his house Philip king of Macedon, who became the patron of his son. So well did the youth approve himself as secretary to the monarch, that his son Alexander continued him in the same office, and gave him a command in the cavalry. According to Plutarch, Eumenes took every advantage that his station afforded him of accumulating money, for his tent being set on fire by the private orders of his sovereign, to whom he had refused the loan of three hundred talents; there was found to the value of more than one thousand talents in melted gold and silver. After the death of Alexander, when the provinces were divided among the principal commanders, the government of Cappadocia, Paphlagonia, and the country bordering on the Euxine sea, as far as Trapezium, which as yet were unconquered, were assigned to Eumenes. Eumenes attached himself to Perdiccas, who made him his chief minister, and gave directions to Antigonus and Leonatus to put him in possession of his government. Antigonus paid no attention to the order, but Leonatus, pretending to comply, marched an army seemingly for the purpose, which Eumenes joined. His design was, however, to seize the kingdom of Macedon for himself; but upon making it known, Eumenes deserted him by night, after seizing his treasures, and repaired to Perdiccas. In reward for his fidelity, Perdiccas himself made an expedition in Cappadocia, and after defeating and killing the king Ariathes, left Eumenes master of the country. He was next appointed prefect of Asia, between mount Taurus and the Hellespont, and was entrusted with the care of opposing the army expected to march against him out of Greece under Antipater and Craterus. On the approach of these great commanders, Eumenes concealed from his army that they were about to contend with Craterus, for whom they entertained the most profound respect and veneration, and giving battle to him and Neoptolemus, he slew the latter with his own hand, while Craterus was mortally wounded, fighting at the head of his phalanx. Eumenes, who felt for him emotions of the sincerest friendship, grasped his hand as he was expiring, wept over his remains, and honoured him with a magnificent funeral. After the murder of Perdiccas by his own army, Eumenes was declared a public enemy, and Antigonus was sent to conduct the war against him. Eumenes was routed, but able to retire to the impregnable castle of Nora, which he defended with great ability. He was abundantly supplied with corn, and though with-

out any other kind of provisions, he kept his men in good humour, by his affable and cheerful demeanour. Another scene opened itself for the ambition of Antigonus, and Eumenes was set at liberty. He instantly began to levy troops, and in a short time was declared royal general of Asia, and there was assigned to him a guard of Argyraspidæ, or silver shields. To inspire his troops with a sort of religious enthusiasm in the cause, he pretended to have seen Alexander in a vision, by whose direction he erected a royal tent, containing a throne of gold, with all the ensigns of majesty, where the captains were to offer incense, and then deliver their orders in a common council. After this there were disputes about the chief command, but when Antigonus approached all agreed that Eumenes was the only general, under whom they would fight. His situation was difficult and precarious, he was aware that many of the other commanders were desirous of getting rid of him, as the chief obstruction to their ambitious designs. From those whom he most suspected he borrowed large sums of money, that by such a pledge he might give them an interest in his security. The war was protracted with various success to a second campaign, when a battle ensued, in which Eumenes routed the enemies' infantry, but in the mean time his cavalry took possession of the camp of Eumenes. This circumstance occasioned so much discontent in the army, that when Antigonus sent an offer to restore the soldiers, their wives and property, on condition of their delivering Eumenes into his hands, the Argyraspidæ surrounded him, seized his sword, tied his arms behind him, and gave him up prisoner. Antigonus being asked how he should be kept? As you would keep a lion or a wild elephant, he replied. All the Asiatic chiefs submitted upon this event, and it remained only to determine the fate of the illustrious captive. This was so long kept in suspense, that Eumenes expressed his surprise that Antigonus had neither the courage to put him to death, nor the generosity to make him his friend by setting him at liberty. A party in the army, headed by Demetrius, favoured the last measure, but the majority urged Antigonus to remove so formidable a rival. This counsel prevailed, and orders were given to deprive him of food. He had suffered the pains of hunger two or three days, and was fast approaching his end, when the army being suddenly obliged to decamp, an executioner was sent to dispatch him. His remains were treated with funeral honours, and his ashes were enclosed in a silver urn, and sent to his family. This was in the year 315 B. C. Eumenes had a fine person, was highly accomplished, and possessed the manners and sentiments suited to an elevated station; he was faithful to the cause of his deceased master, and it was not till after his death that the captains who divided the Macedonian empire among them openly assumed the style of independent sovereigns. Eumenes perished in his forty-fifth year. Univer. Hist. Plutarch.

**EUMENES II.** king of Pergamus, succeeded his father Attalus in the year B. C. 197. He cultivated the friendship of the Romans, who were now beginning to extend their influence into Asia, urging them to check the ambitious projects of Antiochus the Great, of which he feared he should be the victim. Eumenes joined his fleet to that of the Romans, and by his personal bravery greatly contributed to a naval victory, which was gained over that king; nor was he less useful at the decisive battle of Magnesia. On account of his important services he was rewarded by an accession to his dominions, of all the countries west of mount Taurus, which had belonged to Antiochus, and also of all the provinces lying between that mountain

and the river Meander, except Lycia and Caria, which were given to the people of Rhodes. Eumenes, now one of the most potent princes in Lesser Asia, was involved in a war with Prusias, king of Bithynia, in which he was defeated both by land and sea. Peace was made, and another contest took place between Eumenes and Pharnaces; in this the latter was obliged to sue for peace. Eumenes now made an alliance with Antiochus, son of his old enemy Antiochus the Great, and in conjunction with his brother Attalus placed that prince on the throne of Syria, from which he had been driven by an usurper. Perseus, king of Macedon, by increasing his military force, excited the jealousy of his neighbours, and Eumenes took a journey to Rome, for the purpose of acquainting the senate with all he had discovered of his dangerous projects. On his return, Eumenes, going to offer sacrifice at the temple of Delphi, had nearly lost his life by assassins hired by Perseus to destroy him. He received so much injury that he was carried almost lifeless on board his ship, and it was generally believed that he was actually dead. Attalus his brother, giving credit to the news, assumed the royal ensigns, and even married the queen Stratonice. Eumenes, after his recovery, gave his brother a friendly reception, advising him not to marry his wife again till it was certain he was dead. From this period he was engaged in contests with the Romans, who began to regard him with suspicion, and it is thought they encouraged Attalus to seize upon his brother's kingdom for himself. Eumenes died in the year 159 B. C. leaving an infant son to the protection of his brother and successor Attalus. Eumenes was liberal, and even magnificent towards his friends. He was a patron of letters, and made considerable additions to the celebrated library of Pergamus. Univer. Hist.

**EUMENES**, an orator; was an Athenian by descent, but was born at Autun in Gaul, where he was for a considerable time professor of rhetoric, and acquired great reputation. He was secretary to the emperors Maximian and Constantius, and was much esteemed by Constantine the Great, whom he harangued in favour of the inhabitants of Autun in 311. He delivered an oration before the prefect of Lyonesse Gaul, in favour of the restoration of the public schools in the province, towards which he nobly offered to contribute his own salary, as secretary, probably, as well as professor. He died about the middle of the fourth century. Fragments of his orations are printed in the "Papegyrici Veteres." Moreri.

**EUMENIA**, in *Ancient Geography*, a town of Asia, in the Greater Phrygia, seated on the Cludrus.—Also, a town of Asia Minor, in Caria.—Also, a town of Thrace, on the confines of Lower Mœsia.

**EUMENIDEIA**, *Ευμενιδαια*, an annual festival observed in honour of the Furies. It was otherwise called *σερμῶν ἑορτή*, because the Athenians called the Furies *σερμῶν θεῶν*, i. e. venerable goddesses.

**EUMENIDES**, in *Antiquity*. See **FURIES**.

**EUMETRES BELI**, in *Natural History*, the name given by the ancients to a gem which the Assyrians held sacred to their god, and which many other nations learned from them to suppose very powerful against magic. Many have supposed this to be the one we now call oculus Beli: but this is an error, since Pliny, in his account of the eumetres, says, that it was of a very fine green. It was probably a gem of the emerald kind, that stone having ever been in very high esteem in the Eastern part of the world, as it is also to this day.

**EUMINACUM**, in *Ancient Geography*, a town of Mœsia,

Mœsia, marked in the Itinerary of Antonine; 24 miles from Viminiacum,

EUMME' FAREGGE', or *Omm Faredje*, a canal of Egypt, joining lake Manzaleh with the Mediterranean; supposed to be the mouth of that ancient canal, called the Tanitic or Saitic branch of the Nile.

EUMOLPIDES, in *Antiquity*, priests of Ceres, who had the power among the Athenians of initiating into the mysteries of this goddess, or excluding from them.

EUMOLPUS, in *Biography*, a disciple of Orpheus, who, tracing the footsteps of his father Musæus, wrote concerning the mysteries of Ceres.

EUNAPIUS, a native of Sardis, in Lydia, flourished in the fourth century, and was a kinsman of the celebrated sophist Chrysanthius, at whose request he wrote the lives of the philosophers of his time. This work has been characterized by Brucker "as a mass of extravagant tales, discovering a feeble understanding, and an imagination prone to superstition;" besides being a sophist, he was an historian, and practised physic. In his writings he seems to have entertained a great prejudice against Christianity, the martyrs to which he treats with a contempt that has given just offence to contemporary ecclesiastical writers. He wrote a history of the Cæsars from Claudius II. to Arcadius and Honorius, of which only a fragment, "De Legationibus," is remaining. The "*Vitæ Philosophorum*" was published with a Latin translation by Junius in 1596. Moreri.

EUNILAK, in *Geography*, a place of East Greenland. N. lat. 61° 4'. W. long. 46°.

EUNOFIUS, a name given by some authors to the ætites, or eagle-stone.

EUNOMIANS, in *Ecclesiastical History*, a sect denominated from Eunomius, bishop of Cyzicus, who, in the fourth century, maintained most of the errors of Arius, and added others to them. He was a native of Dacora, a town of Cappadocia, and removing to Constantinople, gained his subsistence first as a notary, and afterwards as a school-master. At Alexandria he became a disciple of Aetius, whose opinions he adopted and strenuously defended. Having been ordained a deacon by Eudoxius, bishop of Antioch, he was deputed to the court of the emperor Constantius for the purpose of defending Eudoxius against the accusations of Basil, bishop of Ancyra; but in his way thither he was seized by the partizans of Basil, and banished to Myda, a city in Phrygia. In the year 360 he was ordained bishop of Cyzicus; but boldly avowing his opinions, he became obnoxious to the orthodox party, and underwent various and severe persecutions. At the command of the emperor Constantius, he was at length condemned and deposed by Eudoxius. At Chalcedon, whither he retired, his enemies pursued him, and he was afterwards banished by the emperor Valens to Mauritania. At the close of the reign of this emperor, after he had been allowed to return to Constantinople, he was charged with disturbing the peace of the church, and again banished to the island of Naxos. When Valens died, he returned to Chalcedon, but was soon sent into exile by the emperor Theodosius. Wearied by incessant and grievous persecution he obtained leave from the court to retire to the place of his nativity, where he died at an advanced age, about the year 394. He was the author of various works, most of which are now lost. Those that are extant are "Eunomius's Creed," presented to the emperor Theodosius in the year 383, and his "Apologeticus," or Defence of his Doctrine, in which, according to Dr. Cave, the sly arch-heretic reasons shrewdly. Fabricius has published this piece entire, and an English version of it may be seen in the 1st volume of Whiston's "*Primitive Christianity reviv-*

ed." Socrates Hist. Eccles. Cave's H. L. Fabr. Bib. Græc. vol. viii. Lardner.

EUNOMIËUPSYCHIANS, a sect of heretics of the fourth century, mentioned by Nicephorus, lib. xii. cap. 30. being the same with those called Eutychiens by Sozomen, lib. vii. cap. 17. See EUTYCHIANS.

EUNUCH, *Eunuchos*, a term applied in the general to all who have not the faculty of generating, either through imbecility or frigidity; but more particularly to such as have been castrated, or have lost some of the parts necessary for that purpose.

The word is formed of *εὐνοῦς*, q. d. *leili curam habet, guardian, or keeper of the bed.*

In England, France, &c. eunuchs are never made but on occasion of some disease which renders such an operation necessary; but in Italy they make eunuchs for the sake of preserving the voice; and in the East they make eunuchs to be guards or attendants on their women.

Great numbers of children, from one to three years of age, are yearly castrated in Italy to supply the operas and theatres, not only of Italy but other parts of Europe, with singers; though it is not one in three, that, after having lost their virility, have a good voice for a recompence. See CONSERVATORIOS.

Tavernier assures us, that in the kingdom of Boutan, in the East Indies, there are every year made twenty thousand eunuchs, and sold thence into other countries.

The seraglios of the Eastern emperors are chiefly served and guarded by eunuchs; and yet we have very good testimonies, that the rich eunuchs in Persia and other countries, keep seraglios for their own use. This is a punishment of crimes in some countries. See ADULTERY.

By an arret of the grand chamber of Paris in 1665, it is adjudged that an eunuch could not marry, not even with the consent of the woman, and all the parties on both sides.

Claudian has a very severe satire against the eunuch Eutropius, who had been elected consul of Rome. He represents him as an old woman, dressed up in the honours of the consulate.

In the council of Nice those were condemned who, out of an indiscreet zeal, and to guard themselves from sensual pleasures, should make themselves eunuchs. Such as thus mutilated their bodies were excluded from holy orders; witness Leontius, bishop of Antioch, who was deposed for having practised this cruelty on himself; and the bishop of Alexandria excommunicated two monks who had followed his example, on pretence of securing themselves from the impetuous motions of concupiscence.

Several of the emperors made very severe prohibitions against the making of eunuchs, or people's castrating themselves. See CASTRATION.

EUNUCHS, *Eunuchi*, in *Ecclesiastical History*, is also the denomination of a sect of heretics in the third century, who had the folly or madness to castrate not only those of their own persuasion, but even all they could lay hands on.

They took their rise from the example of Origen, who, upon a misunderstanding of our Saviour's words in St. Matthew, chap. xix. ver. 12. made himself an eunuch, by cutting off the offending part, as some say; or as others (particularly St. Epiphanius), by the use of certain medicines. These heretics were also called *Valesians*.

EVOCATI, among the Romans, soldiers, who having served their time in the army, went afterwards volunteers at the request of some favourite general.

EVOCATION, *Evocatio*, among the Romans, a religious ceremony always observed by them at undertaking  
the

the siege of a town, wherein they solemnly called upon the gods and goddesses of the place to forsake it and come over to them. Without the performance of this ceremony, they either thought that the place could not be taken, or that it would be a sacrilege to take the gods prisoners.

The form of evocation used at taking the city of Carthage is related by Macrobius, Sat. III. 9.

They always took it for granted that their prayer was heard, and that the gods had deserted the place and came over to them, provided they were able to make themselves masters of it. The ancients had also two other sorts of evocation; one was a magical operation, which they used in order to call up departed souls. This custom of raising the manes, or conjuring up souls departed, was so ancient, that its origin is traced as high as the earliest periods of time; and all the anathemas denounced by the sacred authors against those who consulted familiar spirits are proofs of the antiquity of this practice. Among the different sorts of magic prohibited by Moses, that of calling up the dead is expressly specified. (See *WITCH* of *Endor*.) Prophane authors look upon Orpheus as the inventor of this art, in evidence of which it is alleged, that the hymns which are ascribed to him are mostly real pieces of conjuration, but it is probable that this practice was derived from the people of the East, and was carried into Greece with other religious ceremonies, by colonies which came and settled here. It is certain, however, that in the time of Homer, this sort of conjuration was practised, as it is mentioned in some passages of the *Iliad*. At that time it was not reckoned odious or criminal, since there were persons who made public profession of conjuring up ghosts, and there were temples where the ceremony of conjuration was to be performed. Pausanias (in *Beot.*) speaks of that which was in Thesprotia, where Orpheus came to call up the soul of his wife Eurydice. Ulysses's travels into the country of the Cimmerians, whither he went to consult the ghost of Tiresias, described by Homer in the *Odyssy* (l. xi.) seems to indicate a kind of conjuration. Historians, as well as poets, have mentioned this species of conjuration. Another sort of evocation was that which was used in calling up the gods. In order to understand this practice, it should be recollected, that it was a doctrine of the Pagan theology, that the gods presided in a peculiar manner over certain places, and that several of these places were under the protection of the same god; and as it was impossible for him to be in them all at the same time, it was necessary to use the ceremony of evocation, when his presence was thought needful. They had hymns proper to this operation, which they called *κλήσεις*, such as were most of those ascribed to Orpheus, and those of the poet Proclus. When they thought the patron god was arrived, they celebrated the festival named *επιδημιας*. As soon as the danger, which made them invoke the gods was passed, they gave them liberty to go any where else; and they had other hymns for celebrating their departure, which hymns were called *αποπερικσεις*.

**EVOCATORIÆ EPISTOLÆ**, among the Romans, letters sent by the emperors to command the attendance of any person; or letters granting licence to any one to wait on the emperor; every person not being allowed this privilege till they had desired and obtained the evocatoriæ epistolæ.

**EUODIA**, in *Botany*, from *ευωδια*, a sweet smell, Forst. Gen. 7. t. 7. See **FAGARA**.

**EVOLI**, in *Geography*, a town of Naples, in Principato Citra; 15 miles E.S.E. of Salerno.

**EVOLVENT**, in *Geometry*, a term which some writers

use for the curve resulting from the evolution of a curve: in contradistinction to the evolute, which is the curve supposed to be opened or evolved.

The evolute always both touches and cuts the evolvent at the same time; the reason is, that it has two of its infinitely small sides in common with the evolvent; or, rather exactly placed on two equal sides thereof; one of them within-side that of the evolvent, *i. e.* on the concave side thereof; and the other on the convex side of its correspondent side; so that the evolute touches the evolvent in two points; whence, instead of being a tangent, it is said to osculate the evolvent; and, hence, it is also called *osculator*, and *circulus osculator*.

There is one, and but one osculator, to each point of the evolvent; but to the same point there is an infinity of other circles which only touch, and do not osculate. The osculator, and the evolute, make no angle in the place where they touch and cut; nor can any curve line be drawn between, as there may between a tangent and a curve.

**EVOLUTE**, **EVOLUTA**, in the *Higher Geometry*, a curve first proposed by Mr. Huygens, and since much studied by the latter mathematicians. See **CURVATURE**.

The evolute is a curve, supposed to be evolved, or opened; and which, in opening, describes other curves.

To conceive its origin and formation, suppose a flexible thread, wound exactly over the convexity of any curve, as *ABCG* (*Plate VI. Analysis, fig. 1.*) and suppose the thread fixed in *G*, and every where else at liberty, to *A*. Now, beginning to unwind the thread from the point, and continuing it to *D*, and, throughout, keeping it tight on the curve surface *ABCG*, when the thread is become quite straight, and is only a tangent, *FG*, to the curve in the point *G*, it is evident the extremity *A*, in its progress to *F*, has described another curve line *ADEF*.

Here, the first curve *ABCG* is called the evolute; each of its tangents *BD*, *CE*, &c. comprehended between it and the curve *ADEF*, called the involute, is called a *radius of the evolute*, or *radius osculi*, *radius osculator*, or *radius of curvature*, of the curve *ADEF*, in the respective points *D*, *E*, &c. And the circles, whereof the osculators *BD*, *CE*, &c. are radii, are called *circuli osculatores* of the curve *ADEF*, in *D*, *E*, &c. And, lastly, the new curve resulting from the evolution of the first curve begun in *A*, is called the *curve of evolution*, or *curve described by evolution*.

**EVOLUTE**, *the radius of the*, then, is the part of the thread comprized between any point where it is a tangent to the evolute, and the correspondent point where it terminates in the new curve. Which appellation, *radius*, is the more proper, as one may actually consider this part of the thread in every step it takes, as if it described an arc of an infinitely small circle, making a part of the new curve, which thus consists of an infinite number of such arcs, all described from different centres, and with different radii.

Every curve, therefore, may be conceived as formed by the evolution of another. And we are to find that, whose evolution formed it; which amounts to the finding of the radius of the evolute in any point; for, as it is always a tangent to the generating curve, it is, properly, no more than one of its infinitely small parts, or sides, prolonged; and all its sides, whose positions are determined of course, are no other than the generating curve itself.

The same thread is also called *radius curvæ*, or *radius osculi*, because a circle described hereby, from the centre *G*, is said to osculate, or kiss it, as both touching and cutting at the same time, *i. e.* touching both the inside and the out.

Hence, 1. The evolute *BCF* (*fig. 35.*) is the place of

# EVOLUTE.

all the centres of the circles that osculate the curve  $AM$ , described by evolution. 2. When the point  $B$  fall on  $A$ , the radius of curvature, or radius of the evolute,  $MC$ , is equal to the arc  $BC$ ; or to the aggregate of  $AB$ , and the arc  $BC$ . 3. Since the element of the arc  $Mm$ , in the curve described by evolution, is an arc of a circle described by the radius  $CM$ ; the radius of the evolute  $CM$  is perpendicular to the curve  $AM$ , or to a tangent at the point  $M$ . 4. Since the radius of the evolute  $MC$  is always a tangent to the evolute  $BCF$ , curves by evolution may be described through innumerable points, if only tangents be produced in the several points of the evolute, till they become equal to their correspondent arcs.

The finding of the radii of evolutes is a thing of great importance in the higher speculations of geometry; and even, sometimes, is of use in practice as the inventor of the whole theory, Huygens, has shewn, in applying it to the pendulum. (Horol. Oscill. part 3.) The doctrine of the oscula of evolutes is owing to M. Leibnitz, who first shewed the use of evolutes in the measuring of curves.

We shall here subjoin a brief account of the method of finding the radius of the evolute in different kinds of curves and equations expressing the nature of evolutes.

1. To form a general expression for  $(BE)$  the radius of the evolute, or of curvature at any point  $B$  in the involute curve  $ABY$ , whose axis is  $AX$ , and evolute  $DE$ , fig. 3.

With the radius  $EB$  describe the circular arc  $BK$ , which will have the same curvature with the involute curve  $AB$  at the point  $B$ . Draw the radius  $EK$  parallel to the axis  $AX$ , and produce the ordinate  $BC$  to  $L$ , to which draw  $AN$  parallel: let the absciss  $AC$  be  $= x$ , the ordinate  $CB = y$ , radius  $EB$  or  $EK = r$ ,  $KN = a$ , and  $NA = b$ ; then  $LE = r - a - x$ . If the absciss  $x$  be supposed to increase uniformly, and  $Bm$  to be a tangent at the point  $B$ ; and  $mn$  be drawn parallel to  $BC$ , and  $BN$  parallel to  $AX$ ;  $Bn, nm$ , and  $mB$ , which are the contemporary increments of the absciss, ordinate, and curve, will be as their fluxions respectively; or  $Bn$  will be as  $\dot{x}$ ,  $nm$  as  $\dot{y}$ , and  $Bm (= Bn^2 + nm^2)^{\frac{1}{2}}$  as  $\dot{x}^2 + \dot{y}^2$ .

Farther, the triangles  $Bnm$  and  $BLE$  are similar; therefore  $Bn : nm :: BL : LE$ , i. e.  $\dot{x} : \dot{y} :: y + b : r - a - x$ ; consequently,  $r\dot{x} - a\dot{x} - x\dot{x} = y\dot{y} + b\dot{y}$ : the fluxion of which equation (supposing  $\dot{x}$  invariable, and therefore, the direction of the curve  $AB$  continually approaching towards a parallelism with its axis, the fluxion of  $\dot{y}$  as negative) is  $-\dot{x}^2 = \dot{y}^2 - y\dot{y} - b\dot{y}$ ; and  $\dot{x}^2 + \dot{y}^2 = b + \dot{y} \times \dot{y}$ .

Again,  $LB : BE :: nB : Bm$ , i. e.  $b + y : r :: \dot{x} : \sqrt{\dot{x}^2 + \dot{y}^2}$ ; therefore  $b + y = \frac{r\dot{x}}{\dot{x}^2 + \dot{y}^2}$ , and substituting this expression for  $b + y$ , the above equation will become  $\dot{x}^2 + \dot{y}^2 = \frac{r\dot{x}\dot{y}}{\dot{x}^2 + \dot{y}^2}$ ; consequently,  $\dot{x}^2 + \dot{y}^2 \times \dot{x}^2 + \dot{y}^2 = r\dot{x}\dot{y}$ , i. e.  $\sqrt{\dot{x}^2 + \dot{y}^2} = r\dot{x}\dot{y}$ , and  $\frac{\dot{x}^2 + \dot{y}^2}{\dot{x}\dot{y}} = r = BE$ . In

deducing this expression, the increment of the ordinate  $y$ , or the velocity or fluxion with which it flows, is supposed continually to decrease, therefore its second fluxion is negative; but when  $y$  increases with an accelerated motion, its second fluxion will be affirmative; and the above expression will be  $\frac{\dot{x} - \dot{y}}{-\dot{x}\dot{y}}$ . By substituting 1 for  $\dot{x}$ , which is in-

variable in these expressions, they will become  $\frac{1 + \dot{y}^2}{\dot{y}}$

and  $\frac{1 - \dot{y}^2}{\dot{y}}$  respectively; the former taking place when

the curve is concave, and the latter when it is convex towards the axis, and the sign of  $\dot{y}$  shewing the position of the evolute and radius of curvature with respect to the curve and axis. By reducing these expressions from the nature and properties of the curve, and always substituting 1 for  $\dot{x}$ , we shall obtain the value of  $BE$ , or the radius required. The vertical distance or radius  $AD$  may be easily obtained by substituting for  $\dot{x}$ , 1, and for  $\dot{y}$  its proper value in the expression

for the subnormal  $CH$ , which is evidently  $\frac{y\dot{y}}{\dot{x}}$ . *E. gr.*

1. To find the radius of curvature at any point  $B$  in the parabola  $AY$ , fig. 4.

Let the parameter be  $= a$ , absciss  $AC = x$ , and ordinate  $CB = y$ : then, by the nature of the curve  $ax = y^2$ , and therefore  $a\dot{x} = 2y\dot{y}$  (see FLUXION), and making  $\dot{x} = 1$ ,  $a = 2y\dot{y}$ , and  $\dot{y} = \frac{a}{2y} = \frac{a}{2 \times ax}^{\frac{1}{2}}$ . But the fluxion of this

equation will be  $-\dot{y} = \frac{-a^{\frac{1}{2}}}{4 \times ax^{\frac{1}{2}}}$ , or  $\dot{y} = \frac{a^{\frac{1}{2}}}{4 \times ax^{\frac{1}{2}}}$ , and  $\dot{y}^2$  being equal to  $\frac{a^2}{4ax} = \frac{a}{4x}$ , we shall have, by substitut-

ing these values in the expression  $\frac{1 + \dot{y}^2}{\dot{y}}$  for  $\dot{y}^2$  and  $\dot{y}$ ,

$$\frac{1 + \frac{a}{4x}}{\frac{a^{\frac{1}{2}}}{4 \times ax^{\frac{1}{2}}}} = \frac{4}{a^{\frac{1}{2}}} \times \frac{4x + a}{4x} \times \frac{1}{ax^{\frac{1}{2}}} = \frac{4}{a^{\frac{1}{2}}} \times \frac{4ax^{\frac{1}{2}} + a^{\frac{1}{2}}x^{\frac{1}{2}}}{4x} = \frac{4}{a^{\frac{1}{2}}} \times \frac{1}{4} \times \frac{4ax + a^2}{4} = \frac{4ax + a^2}{2a^{\frac{1}{2}}}$$

Then if a semicircle be described through the point  $B$ ,  $Cn$  be bisected in  $H$ , and  $HR$  be made equal  $2AC$ , and  $RE$  be a perpendicular at  $r$ , produced till it meets a line  $BE$ , drawn from  $B$  through  $H$ , this line  $BE$  will be the radius of curvature required: for  $BC^2 = AC \times Cn$ , 35. E. 3. or  $\frac{AC}{BC} = Cn$ , i. e.  $\frac{ax}{x} = a = Cn$ , and  $CH = \frac{1}{2}a$ , and

$Cr = \frac{1}{2}a + 2x$ ; and by 47 E. 1.  $CH^2 + CB^2 = BH^2$ , i. e.  $\frac{1}{4}a^2 + ax = BH^2$ ; and by 4 E. 6.  $CH : HB :: Cr : BE$ ; i. e.  $\frac{1}{2}a : \frac{1}{2}a^2 + ax :: \frac{1}{2}a + 2x : \frac{a + 4x}{a}$

$\times \frac{a^2 + 4ax}{2a^2} = \frac{a^2 + 4ax}{2a^2} = BE$  as before.  $AD$  the vertical distance, or,  $\frac{y\dot{y}}{\dot{x}}$ , is in this case, putting  $\frac{a}{2y}$  for  $\dot{y}$ ,

and 1 for  $\dot{x}$ , equal to  $\frac{a}{2}$ ; and this likewise appears, by con-

sidering; that in the expression for the radius when the radius becomes equal to the vertical distance, the absciss  $x$  vanishes,

and it becomes  $\frac{a^2}{2a^2} = \frac{a^2}{2a^2} = \frac{a}{2}$ .

*E. gr.* 2. To find the radius of curvature at any point  $B$  in the cycloid  $ABD$ , fig. 5.

Put the radius  $OF$  or  $OD = a$ , absciss  $AC = x$ , ordi-

nate

EVOLUTE.

nate  $CB = y$ , sine  $IG = s$ , and arc  $FG = z$ . Now by 35 E. 3.  $IG = DI \times IF)^{\frac{1}{2}}$ , that is,  $s = \sqrt{2ay - y^2}^{\frac{1}{2}}$ ;

the fluxion of which equation is  $\dot{s} = \frac{ay - yy'}{2ay - y^2}^{\frac{1}{2}}$ ; and by the nature of the cycloid, arc  $DG = GB$ ; and therefore, arc  $FG = GI + AC$ , or  $AC = arc FG - GI$ , that is,  $z = z - s =$  (by substituting for  $s$  its above value)  $z - \sqrt{2ay - y^2}^{\frac{1}{2}}$ ; and the fluxion of this equation, making  $\dot{x} = 1$ , is  $\dot{z} = \dot{z} + \frac{yy' - ay}{2ay - y^2}^{\frac{1}{2}}$ .

But  $\dot{z} = \sqrt{s^2 + y^2}^{\frac{1}{2}} =$  (by writing for  $s$  its above value),

$$\frac{ay - y^2}{2ay - y^2}^{\frac{1}{2}} + y = \frac{ay}{2ay - y^2}^{\frac{1}{2}}; \text{ which, substituted}$$

for  $\dot{z}$ , makes the above equation  $1 = \frac{ay}{2ay - y^2}^{\frac{1}{2}} +$

$$\frac{yy' - ay}{2ay - y^2}^{\frac{1}{2}}; \text{ that is, } 1 = \frac{yy'}{2ay - y^2}^{\frac{1}{2}}; \text{ therefore, } y =$$

$\frac{2ay - y^2}{y^2}$ ; and the fluxion of this equation

(the fluxion of  $y$  being negative), is  $-\dot{y} =$

$$\frac{ay\dot{y} - y^2\dot{y}}{2ay - y^2}^{\frac{1}{2}} - \dot{y} \cdot \frac{2ay - y^2}{y^2}^{\frac{1}{2}} = \frac{-ay}{y^2} =$$

(by writing for  $\dot{y}$  its equal),  $-\frac{a}{y^2}$ ; that is,  $\dot{y} = \frac{a}{y^2}$ .

Now, by substituting  $\frac{2ay - y^2}{y^2}$  for  $y^2$ , and  $\frac{a}{y^2}$  for  $\dot{y}$ ,

$$1 + \frac{2ay - y^2}{y^2}^{\frac{3}{2}} \times \dot{y}^2 =$$

$$\text{we have } \frac{1 + \dot{y}^2}{\dot{y}} = \frac{1 + \frac{2ay - y^2}{y^2}^{\frac{3}{2}} \times \frac{a^2}{y^4}}{\frac{a}{y^2}} =$$

$$\frac{2ay}{ay} = \frac{2ay \times 2ay}{ay}^{\frac{1}{2}} = 2 \cdot 2ay^{\frac{1}{2}} = BE, \text{ the}$$

radius of curvature required.

*Construction.*—Make  $FH = GB$ ; and through the point  $H$  draw the right line  $BE$ , making  $BH = HE =$  chord  $FG$ ; then will  $BE$  be the radius of curvature at the point  $B$ ; for a tangent to the point  $B$  is parallel to the chord  $DG$ , and the radius of curvature is always perpendicular to the tangent; therefore, because by 31 E. 3. the  $\angle DGF$  is right,  $BE$  must be parallel to the chord  $FG$ . Now, by 4 and 8 E. 6.  $DF : FG :: GF : FI$ , or  $CB$ ,  $\therefore GF = DF \times CB)^{\frac{1}{2}} = 2ay)^{\frac{1}{2}}$ , and  $2GF = 2 \cdot 2ay)^{\frac{1}{2}} = BE$ .

2. To form a general expression for the radius of curvature in spirals, or curves whose ordinates are referred to a fixed or central point:

Let  $CBY$ , (*fig. 6.*) be the curve,  $C$  the central point, or that from which all the ordinates issue; and  $BE$  the radius of the curvature at the point  $B$ , that is, let the point  $E$  be supposed in the evolute curve: conceive  $Cb$  and  $Eb$  indefinitely near to  $CB$  and  $EB$ , that is, let the points  $B$  and  $b$  be supposed indefinitely near to each other; and let  $Cf$  and  $Cf'$  be perpendicular to  $EB$  and  $Eb$  respectively, then will the points  $F$  and  $f$  be indefinitely near to a coincidence; and therefore  $Bf$  and  $Cf$  may be taken as equal to  $Bf$  and  $Cf$ . Now, if, with the

ordinate  $CB$  as a radius, the little circular arc  $Bn$  be described and considered as a little right line perpendicular to  $Cb$ , and the increment  $Bb$  be considered as coinciding with the tangent to the point  $B$ , then the little right-angled triangle  $Bnb$  will be similar to the right-angled triangle  $BFC$ ; (for  $\angle CBn = \angle EBb$ ; and therefore  $\angle EBn$  being common, the  $\angle CBF = \angle nBb$ ; and, consequently, the angles at  $F$  and  $n$  being right,  $\angle BCF = \angle Bbn$ ); therefore by 4 E. 6.  $bB : Bn :: CB : BF$ ; that is, (if we put the ordinate  $CB = y$ ,  $Bn = x'$ , and  $nb = y'$ , when, by 47 E. 1  $Bb$

will be  $= \sqrt{x'^2 + y'^2}$ ),  $x' : y :: y : \frac{x'y}{\sqrt{x'^2 + y'^2}}$

$= BF$  or  $Bf$ ; and  $Bb : bn :: BC : CF$ , that is,

$$\sqrt{x'^2 + y'^2}^{\frac{1}{2}} : y' :: y : \frac{yy'}{\sqrt{x'^2 + y'^2}} = CF$$
 or  $Cf$ ; the increment of which is  $rf$ ; that is, supposing  $x'$  to be invariable)  $\frac{y' \dot{y}}{x'^2 + y'^2}^{\frac{1}{2}} - y' y' \times \frac{y y'}{x'^2 + y'^2}^{\frac{1}{2}} =$

$$\frac{x'^2 y'^2 + y'^4 + y x'^2 y''}{x'^2 + y'^2}^{\frac{3}{2}} = rf.$$
 Again, the triangles

$E B b$  and  $E r f$  being similar,  $Bb - rf : Bb :: (BE - rE, \text{ or } rB : BE$ ; that is,  $(\frac{x'^2 + y'^2}{x'^2 + y'^2})^{\frac{1}{2}} -$

$$\frac{x'^2 y'^2 + y'^4 + y x'^2 y''}{x'^2 + y'^2}^{\frac{3}{2}} = \frac{x'y}{x'^2 + y'^2}^{\frac{1}{2}} : \frac{y \cdot x' + y^2}{x'^2 + y'^2}^{\frac{3}{2}}$$

$= BE$ , or  $BE = \frac{y \times x' + y^2}{x'^2 + y'^2}^{\frac{3}{2}}$ ; which is a general expression for the radius of curvature of all curves referred to a fixed or central point, when  $x'$  or  $\dot{x}$  is invariable.

Hence, if  $\dot{x}$  be made  $= 1$ , the general expression for the radius of curvature will be  $= \frac{y \times 1 + \dot{y}^2}{1 + \dot{y}^2 - y\ddot{y}}$ . Wherefore, if we put the equation of the given spiral into fluxions, making  $\dot{x} = 1$ , and put this fluxional equation into fluxions again; and from thence, or from the nature of the curve, find the values of  $\dot{y}^2$  and  $\ddot{y}$ ; then, if for  $\dot{y}^2$  and  $\ddot{y}$  we substitute these their values in this general expression, we shall have  $BE$  the radius of curvature required.

Otherwise. Let  $ARB$  be the proposed curve, (*fig. 7.*)  $P$  the point, or centre, to which its ordinates are referred.  $NOL$  the evolute, and  $RO$  the ray of curvature at  $R$ . Moreover, let  $PH$  be perpendicular to  $RO$ ; and supposing the ordinate  $PR$  ( $y$ ) to become variable by the motion of the point  $R$  along the curve, let the fluxions of  $A R$  and  $P H$  ( $\rho$ ), expressing the celerities of the points  $R$  and  $H$  in directions perpendicular to  $RO$ , be denoted by  $\dot{z}$  and  $\dot{\rho}$  respectively: the fluxions of quantities being always as the celerities by which the quantities themselves increase in magnitude. (See FLUXION).

Therefore the celerities of any two points, in a right line revolving about a centre, being as the distances from that centre, it follows that  $\dot{\rho} : \dot{z} :: OH : OR$ ; whence by division (putting  $RH = v$ ) we have  $\dot{z} - \dot{\rho} : \dot{z} :: v - (RH) : RO = \frac{v\dot{z}}{\dot{z} - \dot{\rho}} = \frac{v\rho\dot{z}}{\rho\dot{z} - \dot{\rho}^2}$ . But  $\dot{\rho} \cdot \dot{z} = y \cdot \dot{y}$ .

and

# EVOLUTE.

and therefore  $RO = \frac{vyj}{yy - p\dot{p}}$ ; which, because  $y^2 - p^2$  is  $v^2$  (and therefore  $y\dot{y} - p\dot{p} = v\dot{v}$ ) will also be  $= \frac{vyj}{v\dot{v}} = \frac{yj}{\dot{v}}$ .

*E. G. 1.* Let the given curve  $AR$  (*fig. 7.*) be the logarithmic spiral, whose nature is such, that the angle  $PRQ$  (or  $RPH$ ) which the ordinate makes with the curve, is every where the same.

Then (denoting the sine of that angle by  $b$ , and the radius of the tables by  $a$ ) we have  $RH(v) = \frac{by}{a}$ , and

therefore  $RO\left(\frac{y\dot{y}}{v}\right) = \frac{ayj}{by} = \frac{ay}{b}$ ; which being to  $PR$

( $y$ ) in the constant ratio of  $a$  to  $b$ , or of  $PR$  to  $RH$ , the triangles  $ROP$  and  $RPH$  must therefore be similar, and so the angle  $POH$ , which the ordinate  $PO$  makes with the evolute, being every where equal to  $PRQ$ , will likewise be invariable. Whence it appears that the evolute is also a logarithmic spiral, similar to the involute; and that a right line drawn from the centre, perpendicular to the ordinate of any logarithmic spiral, will pass through the centre of curvature.

*E. G. 2.* To find the radius of curvature at any point  $B$  the spiral of Archimedes,  $CB$ , &c. *fig. 8.*

Put the circumference of the generating circle  $AF$ , &c.  $= a$ , and its radius  $CA = b$ , ordinate  $CB = y$ , arc  $AF = z$ . Let  $Cf$  be supposed indefinitely near to  $CF$ , that is, let the  $\angle FCf$  be supposed indefinitely small; and with the ordinate  $CB$  as a radius describe the little circular arc  $Bn$ , which put  $= x'$ ; also put  $Ff = z'$ . Now, by the nature of the curve,  $a : b :: z : y$ , or  $z = \frac{ay}{b}$ , the fluxion of which equation is  $\dot{z} = \frac{a\dot{y}}{b}$ ; and by the similar sectors  $CBn$  and  $CFf$ ,  $y : x' :: b : z' = \frac{bx'}{y}$ , or,  $\dot{z} = \frac{b\dot{x}'}{y}$ . Hence,  $\frac{a\dot{y}}{b} = \frac{b\dot{x}'}{y}$ ; that is, (making  $\dot{x} = 1$ )  $\frac{a\dot{y}}{b} = \frac{b}{y}$ ; from which equation we have

$$j = \frac{b^2}{ay}; \text{ therefore } j^2 = \frac{b^4}{a^2y^2}, \text{ and } \dot{j} = \frac{-ab^2\dot{y}}{a^2y^3} =$$

(by writing for  $j^2$  its value),  $\frac{-b^4}{a^2y^2}$ ; and if we substitute

for  $j^2$  and  $\dot{j}$  these their values, we shall have  $\frac{y \times 1 + \dot{y} \times \frac{1}{2}}{1 + y^2 - yj}$

$$= \frac{y \times 1 + \frac{b^4}{a^2y^2}}{1 + \frac{b^4}{a^2y^2} + \frac{b^4}{a^2y^2}} = \frac{ay^2 + b^4}{a^2y^2 + 2ab^2} = BE, \text{ the radius of curvature sought.}$$

*Construction.*—Through the centre  $C$  draw the indefinite right line  $Hv$  perpendicular to the ordinate  $CB$ ; draw the tangent  $TB$ , perpendicular to which draw  $BH$ ; produce  $BC$  to  $V$ , making  $BR = TH$  and  $RV = CH$ ; with  $BV$  and  $BR$  as radii, describe the arcs  $Vv$  and  $Rr$ ; draw the right line  $vB$ ; and from the intersecting point  $r$  draw  $rE$  parallel to  $vH$ ; then will  $BE$  be the radius of curvature at the point  $B$ : for,  $CT = \frac{y\dot{z}}{b}$ , that is, by substituting  $\frac{ay}{b}$  for  $z$ ,  $CT$

$= \frac{ay^2}{b^2}$ ; and by 8 and 4 E. 6.  $TC : CB :: CB : CH$ , that is,  $\frac{ay^2}{b^2} : y :: y : a = CH$ ; therefore  $TH = BR = Br = \frac{ay^2}{b^2} + \frac{b^2}{a}$ , and  $BV = Bv = \frac{ay^2}{b^2} + \frac{2b^2}{a}$ ; and by 47 E. 1.  $HB = \sqrt{BC^2 + CH^2} \times \frac{1}{2} = \sqrt{b^2 + \frac{a^2y^4}{b^2}} \times \frac{1}{2} = \frac{a^2y^2 + b^2}{a}$ ; again, by 4 E. 6.  $Bv : BH :: Br : BE$ , that is,  $\frac{ay^2}{b^2} + \frac{2b^2}{a} : \frac{a^2y^2 + b^2}{a} :: \frac{ay^2}{b^2} + \frac{b^2}{a} : \frac{a^2y^2 + b^4}{a^2y^2 + 2b^2} = \frac{a^2y^2 + b^4}{a^2y^2 + 2ab^2} = BE$ .

3. To find an equation that shall express the nature of the evolute of a given involute curve.

Let  $BE$  be the radius of evolution or curvature at any point  $B$  in the involute curve  $AB$ , *fig. 9.* whose absciss is  $AC = x$ , and ordinate  $CB = y$ . Parallel to  $HA$  draw  $EN$ ; produce  $BC$  to  $L$ ; and equal and parallel to  $CL$ , draw  $DN$  from the vertex of the evolute  $DE$ ; then will the triangles  $BHC$  and  $BEL$  be similar: and therefore, by 4 E. 6.  $BH : HC :: BE :$

$EL$ , that is,  $\frac{\dot{y}}{x} \times \sqrt{x^2 + y^2} \times \frac{1}{2} : \frac{y\dot{y}}{x} :: \frac{x^2 + y^2}{x\dot{y}} : \dot{y}$

$\times \frac{x^2 + y^2}{x\dot{y}} = EL$ ; and  $HC : CB :: EL : LB$ , that

is,  $\frac{y\dot{y}}{x} : y :: \dot{y} \times \frac{x^2 + y^2}{x\dot{y}} : \frac{x^2 + y^2}{\dot{y}} = LB$ . Now, these are general expressions for  $EL$  and  $LB$ , when  $\dot{x}$  is considered as invariable, and the fluxion of  $y$  as negative. Hence, therefore,

If  $\dot{x} = 1$ , and the fluxion of  $y$  be negative, the general expression for  $BL$  will be  $= \frac{1 + j^2}{j}$ , and this multi-

plied by  $\dot{y}$  is  $\dot{y} \times \frac{1 + j^2}{j} =$  the general expression for

$LE$ . Now, by help of the equation of the given involute curve, exterminate  $j$ ,  $j^2$ , and  $\dot{y}$ , out of these expressions, and find the vertical distance  $AD$ . Then, if we put the absciss of the evolute  $DN = u$ , and its ordinate  $NE = v$ ; by help of these two equations,  $u = BL - BC$ , and  $v = AC - AD + LE$ , we may get the nature of the evolute curve  $DE$  required.

*Note.*—If the given involute be convex towards its axis, and  $x$  and  $y$  increase together, or the fluxions of  $x$  and  $y$  be both affirmative, then the general expressions for  $BL$  and  $LE$  will be  $\frac{1 + j^2}{-j}$ ; and  $\dot{y} \times \frac{1 + j^2}{-j}$  respectively; wherein the negative sign shews, that the points  $L$  and  $E$  must be taken on the concave side of the involute curve, that is, on the other side of it with regard to  $x$  and  $y$ .

*E. gr.* To find the nature of the curve  $AEP$  (*fig. 10.*) by whose evolution the cycloid  $ABD$  is described.

Put  $AC = x$ ,  $CB = y$ , arc  $FG = z$ , and  $OD$  or  $OF = a$ ; then by Ex. 2. art. 1. above,  $j = \frac{2ay - y^2}{y}$   
 $j^2 = \frac{2ay - y^2}{y^2}$ , and  $\dot{y} = \frac{a}{y}$ ; wherefore,  $BL =$

$$\frac{x + y^2}{y} = \frac{1 + \frac{2ay - y^2}{y^2} \times y^2}{a} = 2y, \text{ and } LE = y \times$$

$$BL = \frac{2ay - y^2}{y} \times 2y = 2 \cdot 2ay - y^2 \frac{1}{2}. \text{ Hence, if}$$

we put the absciss AN = u, and ordinate NE = v, we have u ( = BL - CB = ) 2y - y = y, and v = ( AC + LE = ) x + 2 \cdot \frac{2ay - y^2}{y^2} \frac{1}{2} that is, (because x = z - \frac{2ay - y^2}{y^2} \frac{1}{2}) v = z + \frac{2ay - y^2}{y^2} \frac{1}{2}, or, (writing u for y its equal,) v = z + \frac{2au - u^2}{u^2} \frac{1}{2}. Wherefore, the evolute curve AEP is a cycloid, and equal to the given cycloid ABD; for, let AS = SV = a, then (AN being = FI,) AT' = FG = z, and NT' = \frac{2au - u^2}{u^2} \frac{1}{2} = IG; and therefore, AT' + TN = z + \frac{2au - u^2}{u^2} \frac{1}{2}, that is, AT' + TN = NE, which is the property of the cycloid; therefore, the evolute AEP is a cycloid; and because AV = FD, therefore the cycloids AEP and ABD are equal. See CYCLOID.

The evolute of a spiral, or indeed of any other curve, may be described by finding the radii of curvature at several points in the involute; for then we shall have as many points in the evolute, through which if a curve line be drawn, it will be the evolute sought.

Wolf. Elem. Math. tom. i. p. 524, seq. or the Infinim. Petites of M. le Marquis de l'Hopital. Simpson's Fluxions, vol. i. p. 71, &c. And Rowe's Fluxions, edit. 3. 1767, chap. vi. and vii. p. 103-132.

Since the radius of an evolute is either equal to an arc of an evolute, or exceeds it by some given quantity, all the arcs of evolutes may be rectified geometrically, whose radii may be exhibited by geometrical constructions; whence we see why an arc of a cycloid is double its chord; the radius of the evolute being double the same, and the evolute of a cycloid being itself a cycloid, equal and similar to the involute.

M. Varignon has applied the doctrine of the radius of the evolute to that of central forces; so that having the radius of the evolute of any curve, one may find the value of the central force of a body; which, moving in that curve, is found in the same point where that radius terminates; or reciprocally, having the central force given, the radius of evolute may be determined. Hist. de l'Acad. Roy. des Sciences, an. 1706.

The variation of curvature of the line described by the evolution of a curve, is measured by the ratio of the radius of curvature of the evolute, to the radius of curvature of the line described by the evolution. See Maclaurin's Flux. art. 402. prop. 36.

EVOLUTE, imperfect. M. Reaumur has given a new kind of evolute, under this denomination. Hitherto the mathematicians had only considered the perpendiculars let fall on the points of the convex side of the curve; if other lines not perpendicular were drawn upon the same points, provided they were all drawn under the same angle, the effect would be the same; that is, the oblique lines would all intersect within the curve; and by their intersections, form the infinitely small side of a new curve, whereof they would be so many tangents.

This curve would be a sort of evolute; and would have its radii; but an imperfect evolute, since the radii are not perpendicular to the first curve. Hist. de l'Acad. &c. an. 1709.

EVOLUTION, in Geometry, the unfolding or opening of a curve, and making it describe an évolvent.

The word *evolutio* is formed of the preposition *e*, out, and *volvo*, I roll, or wind; q. d. an *unwinding*, or *unrolling*.

The equable evolution of the periphery of a circle, or other curve, is such a gradual approach of the circumference to rectitude, as that its parts do all concur, and equally evolve, or unbend; so that the same line becomes successively a less arc of a reciprocally greater circle, till at last they change into a straight line. In the Philosophical Transactions, N<sup>o</sup> 260, a new quadratrix to the circle is found by this means, being the curve described by the equable evolution of its periphery.

EVOLUTION, in Algebra, is also used for the extraction of roots out of powers. In which sense it stands opposed to involution. See EXTRACTION of roots.

EVOLUTION, as relating to Military operations, must be understood to be founded on the principles of TACTICS (which see), and be considered indispensably necessary to the safety, the progress, and the success of all bodies of men, whether large or small. The term is generally used as synonymous with manœuvre, but in strictness they are by no means to be so accounted; for an evolution rather relates to an open, candid, and undisguised movement, made either for a change of position, or for the general purposes of attack and defence; while a manœuvre applies abstractedly to deceptive movements, to feints, and to that kind of trick which gives rise to the saying so common among us, "I have out-manœuvred him." Thus the French, from whom we have directly borrowed the term, say, "un rusé manœuvre," i. e. a cunning fellow; and among them a skilful seaman is designated "un manœuvrier."

In every service, both in the military and naval departments, certain regulations exist which direct, that all candidates for promotion should be acquainted, not simply with the several motions of the firelock, and the ordinary duties of individuals, but with a variety of movements to be made by entire battalions, or armies, and by either single ships, squadrons, divisions, or fleets respectively. It being our intention to amplify under the head of TACTICS, military and naval, we shall in this place confine ourselves to those evolutions which, forming a part of the British discipline, ought to be thoroughly understood by every person whose pursuits tend towards the goal of martial celebrity; and should be thoroughly understood by every officer, of whatever rank.

The following nineteen changes will be sufficient for the purpose, under the remark, that we presuppose a battalion to be arranged at close order, and all in readiness for performing the required evolutions.

Evolution 1.

On a rear division.	{	Form close column of companies behind grenadiers.	Explanation.—The column marches quick, 20 or 30 paces to the right, and, without halting, begins to deploy into line on the rear division. The commanding officer of the battalion gives the word, for each division to halt, front.
		Form close column of two companies.	
		Face and march to the right.	
		Deploy on the rear division.	

Evolution 2.

On a front division.	{	Form close column of companies in front of the left.	The column marches quick, 30 or 40 paces to the left, and, without halting, begins to deploy on the front division. The commanding officer of the battalion gives the word for each division to halt, front.
		Form close column of two companies.	
		Face and march to the left.	
		Deploy on the front division.	

# EVOLUTION.

## Evolution 3.

On a central division.

Form close column of companies on a central company, either flank in front, and facing to the rear. Countermarch of each division in close column. Deploy on any central named company.

The close column is formed facing to the rear. It then countermarches each division, so as to return to the proper front. In the central deployment by companies, the company officers give the words respectively to halt, front.

## Evolution 4.

Change of position in open column.

Wheel back into open column of companies, the right in front. March forward 30 or 40 paces. Enter an oblique line (the three or four leading companies), by wheeling successively to the left, a half-wheel. Halt. The rear companies file into column. Wheel up into line.

The battalion, thus, at an intermediate point, enters an alignment, on which it is to form.

## Evolution 5.

Wing thrown back.

The left company is wheeled back till parallel with the original position. The rest of the companies wheel into echelon. March to the rear. Form on the left company.

The whole companies wheel back at the same time; the left company twice the number of paces that the others do. Should it be necessary for the subsequent movements, the line may retire 50 or 60 paces, and then front.

## Evolution 6.

Countermarch, and change of position.

Wheel back into open column, the right in front. Countermarch companies by files. March in column 30 or 40 paces. Head division halts close to the head of column. Form square, and prepare for firing. Re-form in close column. Open out to open column from the rear, and halt. Change head of column, by the countermarch of companies, from the rear to the front. Column moves on and halts. Wheel up into line.

After the countermarch by files, the column stands with its left in front. The column closes in quick time. The square is formed, and close column re-formed. The column opens out in quick time from its rear division, and halts. The countermarch by companies, from the rear to the front, is in ordinary time. When the line is formed, it is then considerably to the reviewing general's right, and with its rear to him.

## Evolution 7.

Countermarch by files on the centre of the battalion. This brings back the battalion to its original front.

## Evolution 8.

March in open column.

Form open column behind the left company, which is put in march when the third company has taken its place in column. The right sub-divisions double. The column halts, and pivots are corrected. Wheel up into line.

The companies that are filing incline towards the head of the column; successively front at their wheeling distances, ascertained as usual by their sergeants; take up the ordinary step, and follow in open column. When the column is marching steadily, the whole sub-divisions double at once, at one command, and again move up at another.

## Evolution 9.

Echelon change of position.

Wheel back into open column, the left in front. The third company is wheeled back, the 8th of a circle, and each of the others 3-16ths of the circle. Form line on the third company by the echelon-march.

The line is thus formed oblique, from open column, on a central company, by the echelon-march.

## Evolution 10.

Change of position.

The left company is wheeled up the 8th of a circle, and each of the others 1-16th. Form line by the echelon-march.

The line thus changes position to the front, on the left company, by the echelon-march.

## Evolution 11.

Change of position.

The battalion faces to the right. March in file 50 or 60 paces. Halts. Wheels up into line, except the light company, which files quickly to the right, and forms behind the colours.

The column of companies is formed by the rear men of each moving up quickly to the left of their leaders, and of each other: the officers move to pivot flanks, and pivots are instantly corrected. The column halts when the colours are opposite to the general.

## Evolution 12.

Retreat in line.

The battalion retires (50 paces). Halts; fronts. Fire twice by companies from centre to flanks. Retreat by alternate companies in two lines (250 paces, each retreat about 50 paces.) Form line. Retreat in line (50 paces). Halt; front.

The light company, being previously subdivided and prepared, acts in the retreat by alternate companies, filling up, or at least occupying the intervals in the first line, and retiring with it to the second, in which it continues to set in like manner, and thus alternately. When the line halts, and fronts, it resumes its place on the left.

Evolution 13.

March to flank in echelon.

Companies make a half wheel to the right. March in echelon, (250 paces.) Wheel back on the march into parallel line. Forward (100 paces.) Halt. Fire thrice by companies, from flanks to centre.

At the word "wheel back intoline," the pivot flanks mark time, and the divisions wheel back in ordinary time. At the proper instant, when the battalion is formed, the commander gives the word "Forward." for the whole to advance by the colours, and to correct any irregularity there may be in the battalion.

[Hitherto the battalion may have been *two* deep, but if its companies can muster ten files each, the corps may now be formed *three* deep.]

Evolution 14.

Movements in the square.

Form square. March the square by the left. Angle of the front face (50 paces.) Halt; form square. March square by the left face. Halt; form square. March square by the rear face. Halt; form square. Fire in square by companies. Form the line.

The square is formed by the echelon march of companies. After the march by the left face, the square is formed when opposite the general. The line is formed by the echelon wheel-up, and march of companies. When the order is given to form line, the light company marches quickly, and places itself two deep, and in two divisions, ten or twelve paces behind the two centre companies.

Evolution 15.

Retiring, and filing to the rear.

Retire in line (100 paces.) File by companies from the proper right. Halt in open column, the right in front. Wheel up into line.

When the line has passed the light company twenty paces, that company extends to cover the centre of the battalion, and follows at 50 or 60 paces distance; and when the column halts to form, the light company passes quickly through and beyond it. The companies file quickly to the rear.

The battalion forms line at the extremity of its ground; the light company 30 paces in its rear.

Evolution 16.

Fire, marching and changing to the front.

Advance in line (50 paces.) File from the right of companies to the front (50 paces.) Halt in open column, the left in front. Wheel up into line. Advance in line (50 paces.) Advance by alternate half battalions, and fire four times.

Before the line advances, the light company quickly forms, extended 30 paces before the centre, and preserves that distance in advancing. When the column halts to form, the light company passes quickly to the rear, and assembles half of it behind each flank, then moves relatively with the flank-companies, till after the charge of bayonets. The alternate half-battalions fire, the two first ranks standing.

Evolution 17.

Charge and pursuit.

Form line. Advance (50 paces.) Fire volley. Advance (50 paces.) Fire volley. Charge bayonets (50 paces.) Halt. Load.

After the volley, bayonets are ported; the battalion advances firm by the centre at the quick step, and at the word "Halt," the front rank comes down to the charging position. The word "Prime and Load" is then given, and the light company, issuing from behind the flanks, pursue, return, and assemble, and join on the left of the battalion.

Evolution 18.

Retiring in line.

Retire in line (100 paces.) Retire by alternate half battalions. Fire four times. Retire in line (100 paces, or more.) Halt. Front.

The whole battalion being assembled, the alternate half-battalions fire, the two front ranks standing.

Evolution 19.

Advance in line and salute.

Advance in line (100 paces.) Halt. Fire two volleys. Port arms at the last one, and half cock. Open ranks. Advance within 50 paces of reviewing general. Halt. General salute.

In the volleys the front rank kneels. The music may occasionally play, and the drums roll, as the line advances. The music will play while advancing at open ranks.

We have selected this portion of the discipline ordered for the British army, because it comprizes sufficient changes to give our readers a correct idea of what are termed *evolutions*. These are so contrived as to be performed on a very moderate extent of ground; each evolution serving to correct any obliquity, or lateral change of position, and confining the regiment within certain limits.

It may be proper to remark, that though the foregoing relate in this instance to a single regiment under review, the whole of the charges may be considered as representing those made by a large army; the several companies being the representatives of regiments, or of larger bodies. See BATTALION.

Fa. Holte, a Jesuit, in 1697, printed a Treatise on Naval Evolutions, in folio. By naval evolutions he means the motions made by a fleet, squadron, or naval armament, in order to put themselves in a proper disposition for attacking the enemy, or defending themselves with the most advantage. See TACTICS.

EVOLVULUS, in Botany, from *evolvo*, to roll out or unfold, in opposition to *Convolutulus*, with which the present genus agrees in habit, except in not having a convoluted stem. Linn. Gen. 152. Schreb. 204. Willd. Sp. Pl. v. 1. 1516. Juss. 134. Class and order, *Pentandria Tetragynia*. Nat. Ord. *Campanacea*, Linn. *Convolutuli*, Juss.

Gen. Ch. *Cal.* Perianth inferior, of five lanceolate, acute, permanent segments. *Cor.* of one petal, regular, wheel-shaped, plaited, slightly five-cleft. *Stam.* Filaments five, capillary, spreading, almost as long as the corolla; anthers rather oblong. *Pist.* Germen superior, nearly globular; styles four, capillary, spreading, the length of the stamens; stigmas

simple. *Peric.* Capsule nearly globular, of four cells and four valves. *Seeds* solitary, roundish, angular on the inner side.

*Eff. Ch.* Calyx of five leaves. Corolla five-cleft, wheel-shaped. Capsule superior, of four cells. *Seeds* solitary.

Willdenow has seven species, five of which were known to Linnæus. Among the latter is *E. linifolius*, Linn. Sp. Pl. 392. (*Convolvulus linifolius*; Am. Acad. v. 4. 306. Sytt. Nat. ed. 10. v. 2. 923. Brown. Jam. t. 10. f. 2.) whence he informs us he derived the above generic character, having the plant alive under his own inspection. It is a small inconspicuous annual, with slender, straight, spreading stems; narrow, lanceolate, hairy leaves; and little, blue, axillary flowers; native of low ground in Jamaica.

The other species have rounder leaves, but otherwise agree very much with the above. They grow in the East or West Indies, and are annuals of humble growth, and no conspicuous attractions, being inferior in beauty to the meanest species of *Convolvulus*.

*E. tridentatus*, Linn. Sp. Pl. 392, is now returned to *Convolvulus*, see that genus, sp. 19.

**EUONYMUS**, *εὐώνυμος* of Theophrastus, so called by antiphrasis, from *εὐώνυμος*, having a good name, because the plant was infamous for its strong fœtid smell, and its poisonous quality to cattle. Spindle-tree. Linn. Gen. 107. Schreb. 148. Willd. Sp. Pl. v. 1. 1130. Juss. 377. Gærtn. t. 113. Class and order, *Pentandria Monogynia*. Nat. Ord. *Dumoseæ*, Linn. *Rhamnii*, Juss.

*Gen. Ch.* Cal. Perianth inferior, flat, in four or five deep, equal, roundish, concave segments. *Cor.* Petals four or five, ovate-oblong, flat, spreading, longer than the calyx. *Stam.* Filaments four or five, awl-shaped, erect, shorter than the petals, inserted, alternately with them, into a glandular receptacle; anthers two-lobed. *Pist.* Germen superior, pointed; style short, simple; stigma obtuse. *Peric.* Capsule succulent, coloured, depressed, with four or five angles, and as many cells and valves. *Seeds* solitary, ovate, each wrapped up in a pulpy arillus.

*Eff. Ch.* Calyx flat. Petals five. Capsule superior, five-sided, coloured, of five cells and five valves. *Seeds* in a pulpy covering.

A genus of extra-tropical shrubs, the produce of Europe, North America and Japan. Willdenow has seven species. They are destitute of hairiness, and have opposite branches and leaves; the latter simple, deciduous, more or less elliptical, entire or toothed, with scarcely any stipulas. Flowers of a dull or greenish hue, in axillary forked panicles, not ornamental. Fruit much more conspicuous and often very beautiful, on account of the pink, waxy hue of the capsule, varying occasionally to white, and orange coverings of the seeds.

*E. Tobira*. Thunb. Jap. 99. (Tobira; Kæmpf. Am. Exot. 796, cum ic.), a native of Japan, has terminal flowers, and in many other respects seems not perfectly to accord with this genus.

*E. europæus*. Sm. Fl. Brit. 262. Engl. Bot. t. 362; and *E. verrucosus*, Jacq. Austr. t. 49; also *E. latifolius*, Jacq. Austr. t. 289; are good examples of it. Linnæus confounded them together as varieties, but Scopoli, and afterwards Jacquin, have well distinguished them. The last species in particular is very remarkable for its warty branches, slender habit, reddish flowers, and small pale capsules, out of which the black seeds, partially clothed with their scarlet arillus, hang by slender threads. The wood of all of them is tough, and used for skewers and spindles. It should be cut in the summer. The fruit serves in many places to decorate churches and rustic kitchens at Christmas-

time. It is reported to be dangerously emetic and purgative.

**EUONYMUS**, in *Gardening*, comprehends plants of the hardy flowering shrubby kind, of which the species cultivated are, the common spindle-tree (*E. europæus*); the warted spindle-tree (*E. verrucosus*); the purple-flowered spindle-tree (*E. atropurpureus*); the ever-green spindle-tree (*E. americanus*); and the broad-leaved spindle-tree (*E. latifolius*.)

The evergreen sort of spindle tree has a variety with variegated leaves.

*Method of Culture*.—All the four more common sorts may be propagated either by seeds, layers, or cuttings of the young shoots; but the evergreen kind requires a different method.

In the first mode, the seeds should be sown in the clumps or borders in the early autumn, covering them well in: In the following autumn the plants should be removed, and set out in nursery rows, being kept well cleared from weeds during the summer. After two or three years growth in this situation, they will be fit to plant out for good, in proper situations.

With respect to the young shoots, they may be laid down in the autumn, a slit being made at the joint placed the deepest in the ground. In the following autumn they will be well rooted, and may be taken off and planted out in the manner of the seedling plants.

The cuttings should be made eight or ten inches in length, and planted in a shady border in the autumn. When they have struck full root, they should be carefully removed, and managed as those raised from the seed.

But the two last methods, and those of budding and grafting, are the only ones by which the green variety can be continued with certainty and success.

With regard to the last species, it is best increased by laying down the young branches after being tongued in the autumn, managing them afterwards in the same manner as the others.

These plants are sufficiently hardy to bear the open air, when planted in warm sheltered situations.

They are all very ornamental plants; the four common sorts producing a fine effect by their berry-like seeds, and the last sort but one by its evergreen leaves; the chief objection to the former kinds being their great aptitude to have their leaves completely eaten up by the caterpillars soon after they are fully expanded.

**EVORA**, or **ELVORA**, anciently *Ebora*, in *Geography*, an ancient, walled and fortified, large but not populous, city of Portugal, the capital of the province of Alentejo, and an archbishop's see, situated on a gentle eminence in a fruitful plain, surrounded by hills, near the centre of the province; 65 miles E. Lisbon. The streets are narrow, crooked, and full of angles. It has no trade or manufactures; but contains five parish churches, twenty-three religious houses, and about twelve thousand inhabitants. The cathedral and other buildings are high and in the Gothic style. This city is said to have been founded by the Phœnicians, and walled round by Sertorius, who supplied the town with water by means of a beautiful aqueduct, (since entirely rebuilt by John III.,) and who, after having resided there for a considerable time, was buried, as tradition reports, in this place. Julius Cæsar constituted it a municipium, and named it *Liberaltas Julia*. It was taken by the Moors in the year 715, and retaken by the Christians under Giraldo, whose heroic conduct is celebrated by Camoens in his *Lusad*, in 1166, and then reduced under the dominion of Alphonso Henriques. In 1540 it was erected into

into an archiepiscopal see by pope Paul III.; and the first prelate founded an university, now fallen into decay. In this city are the remains of a temple of Diana, 7 pillars of which are standing, of the Corinthian order, connected by a plaster-wall. This edifice, at first a pagan place of worship, was converted into a Moorish mosque, and is now the butchers shambles. There are many other Roman vestiges, inscriptions, &c. particularly in the great square, which indicate the antiquity of this place. Its fortifications are 12 bastions, and two demi-bastions, and a castle in ruins. On the north side of Evora the hills rise, being round the town adorned with gardens, and on their summits with evergreen oaks. The road from hence to Montemor o novo, which lies at the distance of five leagues, passes over granite hills, partly covered with corn fields, and partly with fine woody or evergreen oaks and pastures. N. lat. 38° 30'. W. long. 7° 42'.

EVORAMONTE, a town of Portugal, in the province of Alentejo, seated on a rock, and containing about 800 inhabitants; 15 miles N.E. of Evora. N. lat. 38° 42'. W. long. 7° 31'.

EVORIA, a town of European Turkey in Livadia; 24 miles N. of Lepanto.

EUOSMA, in *Botany*, from *εὐοσμος*, *sweet-smelling*, because the flowers have the scent of hawthorn-blossoms. Jackson in Andr. Repof. t. 520. Class and Order, *Pentandria Monogynia*. Nat. Ord. *Rotacea*, Linn. *Gentiane*, Juss.

Gen. Ch. *Cal.* Perianth inferior, in five deep, obovate, concave, equal, permanent segments. *Cor.* of one petal, bell-shaped; tube dilated, as long as the calyx, pervious; limb in five broad, short, obtuse, spreading lobes. *Stam.* Filaments five, awl-shaped, shorter than the tube, inserted into its lower part, alternate with the lobes of the limb; anthers incumbent, roundish, compressed. *Pist.* Germen superior, oval, two lobed; style very short and thick; stigma capitate, four-lobed, on a level with the anthers. *Peric.* Capsule ovate, pointed, with a longitudinal furrow on each side, swelling irregularly from the projection of the seeds, of two valves, whole inflexed edges divide it into two cells; receptacles one in each cell, linear, triangular, parallel to the valves and close to the partitions. *Seeds* five or six in each cell, in two rows, oval, flattened on the inner side, all over rough with minute tubercles.

Ess. Ch. Calyx deeply five-cleft. Corolla bell-shaped, with a five-cleft border. Stigma four-lobed. Capsule superior, with two furrows and two cells, bursting at the top. *Seeds* several, oval, rough, affixed to a triangular receptacle.

1. *E. albiflora*. Andr. Repof. t. 520. Native of New South Wales, in the country near Port Jackson, from whence specimens and seeds were long ago sent by Dr. White. It is said to bear our winters in the open ground, flowering in April. *Stem* shrubby, with numerous, opposite, slender, square, leafy, slightly downy branches. *Leaves* opposite, on short stalks, lanceolate, acute, entire, smooth; shining and deep green above; paler, opaque, and somewhat glaucous beneath. *Stipulas* small, brittle-shaped, in pairs at the base of each footstalk, somewhat hairy. *Flowers* in dense, axillary, bracteated panicles, much shorter than the leaves; snow-white, small, but copious, and very fragrant. *Capsules* about a quarter of an inch long, obtuse, rugged, tipped with the short permanent style.

The characters above given will, we believe, distinguish this genus from *Exacum*, to which it is most allied of any in the same natural order. See *EXACUM*.

EVOVÆ, a barbarous word, says Rousseau, formed of

the six vowels, which begin the syllables of the words *seculorum amen*, and which is only used in canto sereno. It is from the letters of this word that the tone is found in the psalms and antiphonaria of the Roman catholic church, and the notes by which the verses of the psalms and canticles must be terminated.

The evovæ always begins by the dominant of the mode and ends upon the final.

EVOUTS, in *Geography*, a small island in the Southern Pacific ocean; 15 miles S. from Terra del Fuego. S. lat. 55° 33'. W. long. 67° 36'.

EUPAREIA, in *Botany*, *εὐπαρεία*, having beautiful checks, in allusion probably to the scarlet colour of the flowers, said to resemble *Anagallis arvensis*. Gærtn. v. 1. 230. t. 50. Schreb. 156. Willd. Sp. Pl. v. 1. 1183. Mart. Mill. Dict. v. 2. Class and order, *Pentandria Monogynia*. Nat. Ord. *Lyfsmachia*, Juss.

Gen. Ch. *Cal.* Perianth inferior, of five lanceolate, acute leaves. *Cor.* Petals from five to twelve, lanceolate, spreading, longer than the calyx. *Stam.* Filaments five; anthers. *Pist.* Germen roundish, superior; style bristle-shaped, long; stigma simple. *Peric.* Berry dry, globose, crowned with the permanent style, of one cell. *Seeds* numerous, roundish, small, affixed to a globose, fungous, central receptacle.

Ess. Ch. Calyx of five leaves. Petals from five to twelve. Berry superior, dry, of one cell, with many seeds. Receptacle globose.

*E. amana* is the only known species, gathered in New Holland by sir Joseph Banks and Dr. Solander. Gærtner describes it as a procumbent plant, resembling *Lyfsmachia nummularia*, but about one-fourth its size. Flowers of the colour of the Scarlet Pimpernel. He adds that "the seed-vessel, which ever way pressed, would not open by regular valves, so that it is very nearly allied to *Trientalis*." Indeed his figures betray the very close affinity, even the identity of these two genera, except that one is described as polypetalous, the other monopetalous, and that the stamens of *Eupareia* are not said to equal the petals in number, when the latter are more than five.

EUPATORIA, formerly KOSLOF, or *Goslove*, in *Geography*, a town and district of Russia, in the province of Taurida or Crim Tartary, near the Black sea. N. lat. 45° 40'. E. long. 33° 14'.

EUPATORIA, or *Pompeiopolis*, in *Ancient Geography*, *Akneschid*, a town in the N.W. part of the Tauris Chersonesus.

EUPATORIA, *Amid*, a town of the kingdom of Pontus, situated in the gulf of Amisa, and contiguous to a town of the same name. Mithridates Eupator is said to have built it, and to have given it his name.

EUPATORIUM, in *Botany*, *εὐπατόριον* of Dioscorides, from Mithridates, surnamed Eupator, who is reported to have brought this plant into use as a counter-poison. Linn. Gen. 413. Schreb. 546. Willd. Sp. Pl. v. 3. 1748. Sm. Fl. Brit. 859. Mart. Mill. Dict. v. 2. Juss. 178. Gærtn. t. 166. Class and order, *Syngenesia Polygamia-aqualis*. Nat. Ord. *Compositae discoidæ*, Linn. *Corymbifera*, Juss.

Gen. Ch. *Common Calyx* oblong, imbricated; scales linear-lanceolate, erect, unequal, unarmed. *Cor.* compound, uniform, discoid; florets all uniform, perfect, fertile, monopetalous, funnel-shaped, with a regular, five cleft, spreading border. *Stam.* Filaments five, capillary, very short; anthers united into a cylindrical tube. *Pist.* Germen minute; style thread-shaped, very long, cloven down as far as the top of the anthers, straight; stigmas slender, bluntish; straight.

straight. *Peric.* none, except the permanent calyx. *Seeds* solitary, oblong, angular; down long, rough, or feathery. *Recept.* naked.

*Eff. Ch.* Receptacle naked. Down rough or feathery. Calyx imbricated, oblong. Style prominent, cloven half way down, divaricated.

A large genus, chiefly, though not entirely, American. The *roots* are perennial. *Stem* sometimes shrubby. *Leaves* opposite, mostly simple, and strongly serrated. *Flowers* corymbose, terminal, numerous, white, bluish, or reddish. Whole plant, roughish, bitter, or aromatic. Willdenow has 71 species.

*E. cannabinum*, Engl. Bot. t. 428, singular for having fingered leaves, which indeed are sometimes found undivided, is the only British species. It grows in watery places about the banks of rivers, or in mountainous boggy thickets, where it with us supplies the place of the Swiss *Cacalia alpina*, which its pink flowers somewhat resemble.

Several of the American species are esteemed in that country, on account of their aromatic and tonic qualities, and known by the name of Fever root, or Fever weed. Among these, we believe, are *E. sessilifolium*, *perfoliatum*, and *aromaticum*, but we want further information on this subject.

*E. Aya-pana*, Venten. Jard. de la Malmaison, t. 3. a native of the banks of the river of the Amazons, is said to be "an excellent sudorific and alexipharmic;" partaking therefore, no doubt, of the virtues of the above-mentioned species. Its *leaves* are lanceolate, nearly entire, and not accurately opposite. The *flowers* are purplish.

*E. zeylanicum*, Linn. Sp. Pl. 1172, has decidedly alternate leaves, so as to have raised a doubt in the mind of Linnæus whether it could belong to this genus; yet its fructification seems altogether like the generality of the species.

EUPEGIUM, in *Ancient Geography*, a town of Greece, in the Peloponnesus.

EUPEN, or OEPEN, in *Geography*, a town of France, in the department of the Ourthe, and chief place of a canton in the district of Malmédy; 4 miles E.N.E. of Limburg. The place contains 6,749, and the canton 12,616 inhabitants, on a territorial extent of 102½ kilometres and seven communes. Here is a considerable manufacture of cloth.

EUPETALOS, in *Natural History*, the name of a gem described by the ancients as famous for its variety of colours. Pliny, lib. xxxii. cap. 10. tells us, that it shewed at once blue, fire-colour, red-lead colour, and yellow. It seems to have been the opal, and that Pliny's description of it in this place was taken from some author he did not perfectly understand, as is the case in many of his accounts from the Greeks.

EUPHASEE, in *Geography*, the ancient name of Hiwassee river in Tennessee, N. America; also the name of an Indian town on its S.W. bank, 28 miles from its mouth. See HIWASSEE.

EUPHEMISMUS, Εὐφημισμός, of *eu*, well, and *φνις*, I speak, in *Rhetoric*, a figure which expresses things in themselves disagreeable and shocking, by terms implying the contrary quality; that is, the Pontus, or Black sea, having the epithet of ἀξυός, (i. e. inhospitable) given it on account of the savage cruelty of those who inhabited the neighbouring countries; this name, by euphemism, was changed into that of Euxinus. Thus Ovid. Trist. lib. iii. eleg. 13.

"Dum me terrarum pars pene novissima Ponti

Euxinus falso nomine dictus habet."

In which sense it only makes a species of irony. But every euphemism is not irony; for we sometimes use improper

and soft terms in the same sense with the proper and harsh. See Voss. Rhet. lib. iv. cap. 186, seq.

EUPHEMIUS, in *Biography*, succeeded to the high dignity of patriarch of Constantinople in the year 490. He was zealously attached to the doctrines of the Catholic church, of which he gave proof by striking out from the lists of persons in communion with the church, the name of Peter Mongus, patriarch of Alexandria, because that prelate had pronounced an anathema against the council of Chalcedon. This circumstance produced a violent schism between the two patriarchs, who convened their respective synods, in which they mutually procured excommunications of each other to be issued. In the year 491, on the death of Zeno, when Anastasius was taking measures to secure the imperial throne, Euphemius warmly opposed him, on account of his known Arian principles, and when he found his opposition fruitless, he refused to crown the new emperor till he had delivered to him a written confession of orthodox faith, and engaged under his hand, and by the sanctity of an oath, to maintain the principles of the Catholic doctrine, as established by the council of Chalcedon. In the year 493, Theodoric, having become master of Italy, sent ambassadors to Anastasius to treat for peace, to which Euphemius was thought to be the chief obstacle. In a short time afterwards Anastasius having confidentially informed the patriarch of his desire to terminate in an honourable manner the war in which he was engaged with the Isaurians, Euphemius betrayed his secret to the patrician John, the father-in-law of Athenodorus, one of the chiefs of the Isaurians. The emperor was made acquainted with the patriarch's conduct, and laid the case before an assembly of bishops, who were convened at Constantinople in the year 495, and by his influence with them, obtained a decree that Euphemius should be deposed, and cut off from the communion of the church. He afterwards obtained a sentence of banishment against Euphemius, who died at Ancyra in the year 515. Moreri.

EUPHON, in *Acoustics*, a musical instrument lately contrived by Dr. Chladni of Wittenberg, who, in consequence of a variety of experiments on the longitudinal vibrations of elastic bodies, constructed this instrument, so called from its pleasant sound, which consists of glass tubes disposed in a proper frame, and expressing their sounds by being rubbed longitudinally. The euphon has some resemblance to a small writing desk. When opened, the glass tubes, of the thickness of the barrel of a quill, and about 16 inches long, are seen in an horizontal position. They are wetted with water by a sponge, and stroked with the wet fingers in the direction of their length, so that the increase of the tone depends merely on the stronger or weaker pressure, and the slower or quicker movement of the fingers. The number of tubes is 42. In the back part there is a perpendicular sounding-board divided in the middle, through which the tubes pass. From this construction it appears, that the euphon should not be considered as an altered or improved harmonica, (See ARMONICA), but as a totally new and different instrument. In regard to sweetness of sound, it approaches very near to the harmonica; but it possesses several advantages, peculiar to itself. It is simpler, with regard both to its construction and the movement necessary for producing the sound, as neither tuning nor stamping is required, but merely the movement of the finger. It produces its sound more speedily; so that as soon as it is touched you may have the tone as full as the instrument is capable of rendering it; whereas in the harmonica, the tones, particularly the lower ones, must be made to increase gradually.

It has also greater distinctness in quick passages, because the tones do not rebound so long as in the harmonica, where the sound of one low tone is often heard when you wish only to hear the following tone. The unison is purer than is generally the case in the harmonica, where it is difficult to have perfect glasses, which in every part give like tones with mathematical exactness. It is however as difficult to be tuned as the harmonica. It does not affect the nerves of the performer; for a person scarcely feels a weak agitation in the fingers; whereas in the harmonica, particularly in concords of the lower notes, the agitation extends to the arms and even through the whole body of the performer. This instrument is less expensive than the harmonica; when one of the tubes breaks, or any other part is deranged, it can soon be repaired, and at very little expence: whereas, when one of the glasses of the harmonica breaks, it requires much time and is very difficult to procure another capable of giving the same tone as the former, and which will correspond sufficiently with the series of the rest. For an account of the experiments that led the author to the construction of this instrument, and of the various stages of his progress in the improvement of it, we refer to the *Philosophical Magazine*, vol. ii. p. 391, &c.

**EUPHONIC ACCENT.** See ACCENT.

**EUPHONY**, in *Elocution and Composition*, that sweet or pleasing quality in the successive sounds of language, which results from happy combinations of the enunciative elements, such especially as, though essentially different in their characteristic powers, melt easily into each other so as to preserve an uninterrupted flow of utterance through the respective members of a sentence, without labour to the speaker, or offence to the hearer. The word is formed of *e*, *bene*, *well*, and *φων*, *vox*, *voice*. Quintilian calls *euphonia*, *vocalitas*; Scaliger, *facilis pronuntiatio*. The most obvious rule with respect to euphonic composition is that a due mixture should be made of consonants and vowels; and the principle of this rule may be at once explained and illustrated by the following parody on a famous but sophistical couplet in Pope's *Essay on Criticism*,

“Your consonants with vowels well combine,  
And twelve small words may flow in one smooth line.”

But this is not all that is requisite for perfect euphony: every vowel does not blend with equal grace and facility with every consonant; nor is every succession of mere vowels, or every succession of consonants, equally offensive or cacophonous. Words or syllables, for example, terminating with thin vowels, may be followed by other words or syllables, commencing with broad or open vowels, or the reverse, with very happy effect; and some consonants may be brought together, in immediate succession, even as terminative and initial elements of following syllables or words, in such way as rather (while they increase the sonorous energy of such composition,) to diversify the time and expression, than to disturb the euphony of the sentence. All the liquids especially (those that properly ought to be, as well as those that commonly are so called) combine with almost equal facility with other liquids, and with vowels or with the consonants, whether semi-liquids, sibilants, or mutes. (See LIQUID, MUTE, &c.). Which of these, and under what circumstances, may be thus brought together, with the happiest effect of euphony and expression, it would require a much longer discussion than we have space for, to ascertain; and, after all, much must be left to the taste, the ear, and the experimental discrimination of the writer. But it is not upon the writer alone, that the effect of euphony depends. The reader or reciter must also do

his part, for though it is very possible so to write, that no organs, and no management of those organs, can elicit in the delivery, any thing but the dissonance of cacophony; there are some pedants who contrive to render even the smoothest compositions harsh and cacophonous, and then ascribe to their native language, (of the very elements and genius of whose oral composition they are utterly ignorant,) the disgusting dissonance which does, in reality, belong to their own jargonized utterance. Euphony in the reader or speaker depends principally upon his skill and management in the articulation and implication of the successive elements, syllables, and words as explained under the term ENUNCIATION; and upon his giving full tune, and sufficient quantity to the liquids and liquifiable consonants. Cacophony (the antagonist of Euphony) on the contrary, results in the reader, from the laboured separation of terminatives and initials, that might easily have been implicated; from giving unnecessary impulse and force to the mutes, from hurrying over the liquids, and partially tuneable elements, as if they were mere mutes, and from perpetual unnecessary interruptions in the stream of enunciative delivery.

**EUPHORBIA**, in *Botany*, *εὐφορβιον* of Dioscorides, so named after Euphorbus, physician to Juba king of Lybia. Spurge. Linn. Gen. 243. Schreb. 326. Willd. Sp. Pl. v. 2. 881. Sm. Fl. Brit. 513. Mart. Mill. Dict. v. 2. Juss. 385. Class and order, *Dodecandria Trigynia*. Nat. Ord: *Tricocca*, Linn. *Euphorbia*, Juss.

Gen. Ch. *Cal.* Perianth interior, of one leaf, inflated, somewhat coloured, with four, in some few instances five, marginal teeth, permanent. *Cor.* Petals, or Nectaries, four, sometimes five, turbinate, gibbous, thick, abrupt, unequal in situation, alternate with the teeth of the calyx, inserted into its margin by their claws, permanent, bearing plenty of honey. *Stam.* Filaments numerous, 12 or more, thread-shaped, jointed, longer than the corolla, inserted into the receptacle, coming to maturity at different periods, separated by bristly scales; anthers roundish, of two distinct lobes. *Pist.* Germen superior, roundish, three-sided, elevated on a stalk above the margin of the calyx; styles three, cloven; stigmas obtuse. *Peric.* Capsule stalked, roundish, three-lobed, of three cells, and three valves which separate elastically. *Seeds* solitary, roundish.

Obsl. The petals or nectaries are for the most part four, in some flowers five, which often happens on the same plant, such flowers being furnished with stamens only, without a pistil, and coming forth earlier than the rest. In many the petals are glandular, in others crescent-shaped, or toothed; in some few thin and membranous; they are commonly situated as it were on the outside of the calyx. The capsule is either smooth, or hairy, or warty.

Ess. Ch. Calyx of one leaf, inflated, inferior. Nectaries four or five, inserted into the calyx. Capsule stalked, three-lobed.

A vast, but very natural, genus, whose species amount in Willdenow's work to 124. They are divided into several sections. All abound with an acrid milk.

Those of the first section have a very peculiar thick, shrubby, fleshy, angular stem, armed with spines, and bearing few or no leaves. To this belongs *E. officinarum*, probably the original species. See its figure in Commelin's Hort. Amit. v. 1. t. 11. Also *E. antiquorum*, ib. t. 12, an East Indian plant, which seems very improperly named, as neither agreeing with the descriptions of the ancients, nor growing in the country whence they procured their *εὐφορβιον*.

The second section has shrubby stems without thorns, neither forked nor umbelliferous. As *E. Caput Medusæ*, Comm.

Comm. Hort. t. 17, common in Green-houses; and *E. petiolaris*, Curt. Mag. t. 883.

The third has forked stems, not umbelliferous, and the plants are mostly herbaceous and annual, as *E. pida*, Jacq. Ic. Rar. t. 477, and *pidulifera*, t. 478; also *E. Peplus*, Engl. Bot. t. 2002, common on the sea shores of the south of Europe.

The fourth has the flowers in an umbel, three-branched in the first instance, and the branches subsequently forked repeatedly, each subdivision of the inflorescence accompanied by a pair of heart-shaped, unequal sided, somewhat coloured bractæus, as our common weed *E. Peplus*, Curt. Lond. fasc. 1. t. 35. Engl. Bot. t. 959.

The fifth has a four-branched umbel, as the great *E. Lathyris* of the gardens, commonly called the Caper tree, remarkable for its long, dark, four-rowed leaves. There are but few species in this section.

The sixth, a numerous section, has a five-branched umbel, like the common *E. helioscopia*, Curt. Lond. fasc. 1. t. 36. Engl. Bot. t. 883; and the rare and splendid *E. punicea*, Sm. Ic. Pict. t. 3, a shrubby Jamaica plant, of which a most miserable specimen is drawn in Jacq. Ic. Rar. t. 484.

The seventh and last section consists of such species as have numerous rays to the common umbel, like *E. Cyparissias*, Engl. Bot. t. 840, frequent in gardens, and *amygdaloides*, t. 256, very common in woods.

EUPHORBIA, in *Gardening*, comprehends plants of the herbaceous, shrubby, succulent kinds, the principal cultivated species of which are; the triangular spurge (*E. antiquorum*); the Canary spurge (*E. canariensis*); the official spurge (*E. officinarum*); the Medusa's head spurge (*E. caput Medusæ*); the myrtle-leaved spurge (*E. tithymaloides*); the seven-angled spurge (*E. heptagona*); the warty-angled spurge (*E. mammilaris*); and the Cape spurge (*E. lathyris*): the first species is a large plant, of which there is a variety with a naked three-cornered compressed stalk, sending out a great number of erect branches, which are likewise generally three-cornered, but sometimes four-cornered; armed with short crooked spines, having no leaves. The plants have not, we believe, yet produced flowers in this climate. This variety, like the species from which it is produced, is a native of the East Indies.

The fourth species has also a variety frequently denominated the "Little Medusa's head," which has a thick short stalk, seldom more than eight or ten inches in height, from which come out a great number of slender trailing branches, about a foot in length, intermixing, and having the same appearance with the other, but smaller and much shorter; the ends are beset with narrow leaves, between which the white flowers come out and appear. Its native situation is the same as that of the species from which it is derived. According to some there are likewise a double branching, a dwarf trailing, and other varieties.

The fifth sort has also laurel leaved and variegated leaved varieties.

*Method of Culture.*—These different sorts of plants may be raised by planting cuttings, which have been made at a joint, five or six inches in length, after having been rolled in sand, and laid upon a shelf for some days to have the wounds healed over, in the summer season about the middle, choosing small pots for the purpose filled with light, dry, sandy mould, with some rubbish at the bottoms, such as that formed of one fourth part of lime-rubbish which has been well screened, the same quantity of sea sand, and one half of the whole of light fresh vegetable earth, which should be very well mixed and incorporated together, by

being often turned over; then plunging the pots in the back hot bed, giving due shade when the weather is hot and sunny, with a little water occasionally once or twice a week. As soon as the plants have stricken root, air should be admitted to them pretty freely in the situation in which they may be; or they may, in order to be hardened, be removed into the stove.

In the after management they should be allowed larger pots annually as they advance in growth, and be often refreshed with water during the summer months, but very sparingly in the winter season.

It may be remarked that most of these sorts of plants are capable of being kept in the hot-house, on the shelves, and some of them, as the fifth, sixth, and seventh sorts, in a dry airy green-house, or glass case, during the winter months, great care being taken to protect them well from the frosts; being set out in the summer in the open air: but the fourth species requires some sort of support in order to prevent the branches, by their weight, forcing it upon the pots; as by this sort of treatment the plants will rise to the height of four or five feet, throwing out a great number of side branches. The eighth kind, however, requires little or no particular care after it has been once introduced, except merely that of keeping the young plants clean, as it will be continued by its scattering the seeds.

All these plants, with the exception of the last, afford great variety in collections of the hot and green-house kinds; and that also in the clumps and borders of the pleasure grounds, among others of the less hardy sorts.

EUPHORBIAE, in *Botany*, the 96th natural order in Jussieu's system, or the 1st of his 15th class. The definition of this class is,—Coryledons two. Petals none. Stamens in a separate flower from the pistils. Its characters are thus more fully explained. Flowers either monoecious, that is, males and females together on the same plant, or dioecious, on separate ones; very rarely hermaphrodite. Calyx in all of one leaf, or a scale supplying its place. Corolla none, except occasionally some scales, or internal divisions of the calyx, resembling petals. In the male flowers the stamens are inserted either into the upper or lower part of the calyx, or scale which supplies its place, definite, or rarely indefinite, in number; their filaments distinct, or rarely united into a central stalk, originating from the middle of the calyx. Germen in the females simple, or sometimes more than one, superior, or rarely inferior; style one, or several, rarely wanting; stigma either solitary or more than one. Fruit either superior or inferior, various in the structure and number of its cells.

The learned author, by his subsequent remarks and explanations, is evidently aware of the difficulties attending this class, which indeed is in no sense really a natural one, its orders having little or no affinity to each other, except the two last *Amentacea* and *Conifera*.

The characters of the order of *Euphorbiae* are, *Flowers* monoecious or dioecious, or rarely hermaphrodite. *Calyx* of each tubular, or deeply divided, simple or double, the internal segments occasionally resembling petals. *Petals* none, except the segments just mentioned. *Stamens*, in the male flowers, definite or indefinite in number, their filaments inserted either into the receptacle, or the centre of the calyx, distinct or united, sometimes branched, sometimes jointed. In some there are chaffy scales between the filaments. *Germen*, in the female flowers, solitary, superior, sessile or stalked; styles in some cases several, often three, with an equal number of cells to the capsule, each containing one or two seeds; in others the style is simple, with three or more stigmas, the fruit of le-

veral cells, equalling the stigmas in number, with one or two seeds in each. In all the cells are furnished with two internally elastic valves; the seeds have a partial covering, and are attached at the upper part to the permanent central axis of the fruit. Coraculum flat, enveloped in a fleshy albumen. The plants are either herbaceous, or shrubby, or arborecent; some of them milky. Leaves alternate or opposite, (in some few instances wanting,) either with or without stipulas. The first section consists of such genera as have several styles, mostly three. These are *Mercurialis*, *Euphorbia*, *Argythamnia* of Brown's Jam. 338. Sw. Prod. 39, *Cicca*, *Phyllanthus*, *Xylophylla*, *Kirganelia*, *Kiggellaria*, *Clusia*, *Andrachne*, *Agyneia*, *Buxus*, *Securinega* of Commerfon, *Adelia*, *Mabea*, Schreb. 641, *Ricinus*, *Jatropha*, *Dryandra*, *Aleurites*, *Croton*, *Acalypha*, *Caturus* and *Excaccaria*. The second section, with a solitary style, contains *Tragia*, *Stillingia*, *Sapium* of Brown, *Hippomane*, *Egopricon*, *Secchium* of Brown, *Hura*, *Omphalea*, *Plukenetia* and *Dalechampia*.

The seeds of these plants are mild and eatable in many instances, if freed from their integuments and coraculum, the latter being very dangerously purgative, as in *Euphorbia* and even *Ricinus*, proving mild in the latter only from the copious oil of the cotyledons. *Euphorbia*, which gives its name to this natural order, can only by a very bold analogy, or rather hypothesis, be said to have no corolla, and is very imperfectly polygamous, not monoecious; indeed Jussieu allows it to be hermaphrodite. See EUPHORBIA.

EUPHORBIVM, is a most acrid gum resin, which exudes from the *Euphorbia officinarum* and other shrubs of the same genus, and was formerly used in pharmacy, but is now nearly, if not, entirely rejected.

This gum is brought from Barbary and other parts of the Mediterranean in tears or drops of an irregular form, generally entangling much impurity; of a pale yellow colour without, and white within. Euphorbium has no smell: when taken into the mouth it gives at first no taste, but after a little time a most acrid biting sensation is felt, which increases to an intolerable degree, and if not immediately rejected it proceeds to corrode the skin of the tongue and fauces. The same acrimony is shewn when applied to the body in any other manner. In reducing it to powder the dust that flies off will excite the most violent sneezing, and often bleeding from the nostrils and throat, so that particular precautions must be taken. When laid for some time on the skin it blisters.

The spirituous tincture of euphorbium is still more acrid.

This gum resin, on account of its extreme acrimony, can hardly be used with safety as an internal medicine, as it is liable to produce violent diarrhoea and bloody stools, and much inflammation. The only purpose for which it has been employed in the later dispensaries has been in mixture with cantharides to increase the vesicating and irritating property, but euphorbium is now altogether disused.

EUPHORIA, in *Botany*, so named by Commerfon from *εὐφορος*, fertile, a genus comprehending the two Chinese fruits Lit-chi and Longan, to which Jussieu suspects Forster's *Pometia* may also belong. See SCYTALIA.

EUPHORY, signifies the same as *Eucrazy*.

EUPHRASIA, in *Botany*, from *εὐφρασα*, to exhilarate, or delight, alluding to the brightness or gaiety of the blossoms. Eye-bright. Linn. Gen. 304. Schreb. 401. Willd. Sp. Pl. v. 3. 192. Tournef. t. 78. Sm. Fl. Brit. 650. Mart. Mill. Dict. v. 2. Juss. 100. Gært. t. 54. Class and order, *Didynamia Angiospermia*. Nat. Ord. *Personate*, Linn. *Pediculares*, Juss.

Gen. Ch. Cal. perianth of one leaf, inferior, cylindrical,

four-cleft, equal, permanent. Cor. of one petal, ringent; tube as long as the calyx; upper lip concave, notched; lower spreading, deeply three-lobed, its lobes equal, obtuse, notched. Stam. Filaments four, thread-shaped, situated close under the upper lip; anthers of two lobes, the lobes unequally spinous at their lower extremities. Pist. Germen superior, ovate; style thread-shaped, agreeing in form and situation with the stamens; stigma obtuse, undivided. Peric. Capsule ovate-oblong, compressed, of two cells and two valves; the partition contrary to the valves. Seeds numerous, minute, roundish, longitudinally striated.

Ess. Ch. Calyx cylindrical, four-toothed, equal. Upper lip of the corolla cleft; lower three-lobed, the lobes cleft. Anthers bearded with unequal spines. Capsule ovate-oblong. Seeds striated.

Botanists are not perfectly agreed about the limits of this genus, and its near allies *Bartsia* and *Rhinanthus*. The first of Willdenow's twelve species, *E. latifolia*, Linn Sp. Pl. 841, is *Bartsia latifolia*, Sm. Prod. Fl. Græc. Sib. 428, a beautiful native of the south of Europe. His sixth, *E. odontites*, is *Bartsia odontites* of Hudf. Fl. Angl. 268, and Sm. Fl. Brit. 648. Engl. Bot. t. 1415.

*E. officinalis*, Linn. Sp. Pl. 841. Engl. Bot. t. 1416. Curt. Lond. fasc. 5. t. 42. common in heathy and mountainous pastures, which its gay blossoms greatly enliven in autumn, is a genuine and original example of the genus. This is a small, upright, annual plant, with ovate sharply serrated leaves. The flowers are white, strongly streaked with purple, having a yellow spot on the lip. On the Alps they are often larger, light purple, and still more beautiful.

The dazzling brilliancy of these little blossoms seems to have given rise to the vulgar opinion, that the plant was good for the eyes; whence its English name Eye-bright.

EUPHRATENSIA, in *Ancient Geography*. See COM-MAGENE.

EUPHRATES of Alexandria, in *Biography*, a Stoic philosopher, who flourished in the second century; was a friend of Dio and of Apollonius Tyanæus, who introduced him to Vespasian. Although a violent quarrel arose between the latter philosopher and Euphrates, in consequence of which Philostratus, the panegyrist of the former, inveighs with great severity against the latter, it appears from the testimony of Epictetus, Pliny the younger, and Eusebius, that Euphrates was universally esteemed for his talents and virtues, and that the censures of Philostratus deserve only contempt. Pliny's character of him is highly interesting. "If ever," says he (Ep. l. i. ep. 10.), "polite learning flourished at Rome, it certainly does at present. Of this I could give you many instances; but I will content myself with naming only Euphrates the philosopher. When, in my youth, I served in the army in Syria, I had an opportunity of conversing familiarly with this excellent man, and took some pains to gain his affection, though that indeed was not difficult; for he is exceedingly open to access, and full of that gentleness of manner which he teaches. Euphrates is possessed of shining talents, which cannot fail to interest even the unlearned. He discourses with great accuracy, dignity, and elegance; and frequently rises into the sublimity and luxuriance of Plato himself. His style is copious and diversified, and so wonderfully sweet, as to captivate even the most reluctant auditor. Add to all this, his graceful form, comely aspect, long hair, and large white beard; circumstances which, though they may probably be thought trifling and accidental, contribute, however, to procure him much reverence. There is no disgusting negligence in his dress; his countenance is grave, but not austere; his approach commands respect, without exciting awe.

With the strictest sanctity, he unites the most perfect politeness of manner. He inveighs against vice, not against men; and, without chastising, reclaims the offender. You listen with fixed attention to his exhortations, and even when convinced, still hang with eagerness upon his lips."

In conformity to the principles of the Stoic philosophy, Euphrates, when he found his strength worn out by disease and old age, voluntarily put a period to his life by drinking hemlock, having first, for some unknown reason, obtained permission from the emperor Adrian. Brucker's *Hist. Phil.* by Enfield, vol. ii.

EUPHRATES, the reputed founder of a religious sect in the second century, sometimes called "Ophians," or "Ophites," and sometimes "Serpentinians," names derived from the peculiar tenet which he held, that the serpent, by which our first parent was deceived, was either Christ himself, or "Wisdom" concealed under the form of that animal, and that he was the occasion of all the knowledge which men had received. Hence he is said to have inculcated a particular veneration for the serpent, preserving a living one, offering to it a subordinate kind of divine honour, and bringing it out to partake of or to consecrate the eucharist. Origen and others contend that the followers of Euphrates were not Christians, but calumniators of Jesus Christ, and opposers of his doctrine: but Dr. Lardner, who has taken some pains in investigating the subject, considers them as believers in Christianity, and maintaining that Jesus, who was born of a virgin, was a most excellent man, and that, having by his miracles and instructions manifested himself to be the true Messiah, was crucified, and afterwards raised from the dead, received into heaven, where he sits on the right hand of God. He conceives that what some have said of them, respecting the serpent being Christ, must be a mistake, founded on an opinion that the brazen serpent in the wilderness was a type or figure of Christ. The other accounts of worshipping the serpent, &c. this judicious and learned writer rejects without hesitation. Moreri. Lardner.

EUPHRATES, in *Ancient Geography*, one of the most considerable and best known rivers of Asia, the source of which was in the mountains of Armenia north of Abus, which after receiving several streams in this part of Armenia, at the towns of Elegia, Gymnias, and Brapus, pursued its course towards the south-west, separating Armenia Major, on the east, from Armenia Minor on the west. It then proceeded south-eastward, washing the skirts of Syria, and dividing Arabia from Mesopotamia; and afterwards directing its course towards the north-east, it separated Chaldæa and Babylonia from Mesopotamia, till at length mixing its waters with those of the Tigris, with which it previously communicated by several canals, it emptied itself into the Persian gulf. The Euphrates, according to Ptolemy, above Babylon, near a town in Mesopotamia, called Siphara, divided itself into two branches, one running to Babylon, and the other to Seleucia, where it fell into the Tigris. Pliny says the latter was partly artificial; for he places Seleucia at the confluence of the Tigris and Euphrates, adding that the Euphrates was conveyed to it by a canal. Prideaux, on the authority of Pliny, ranks this artificial branch among the stupendous works of Nebuchadnezzar. Between these two branches a canal was cut from the Euphrates, above Babylon, to the Tigris at Apamea, 60 miles below Seleucia. This canal was denominated *Naarmalecha*, and was dug by Nebuchadnezzar, as Abydenus informs us, to convey the waters of the Euphrates, when it overflowed, into the Tigris, before they reached Babylon. At the distance of 800 furlongs from Babylon to the south was another canal, called by Arrian Pallacopes, and by Appian Pallacotta,

derived from the branch of the Euphrates that passed through Babylon, and continued to certain lakes or marshes in Chaldæa. On this canal, or river, as Arrian calls it, Alexander sailed from the Euphrates to the above-mentioned lakes. But it is impossible, at this distance of time, and after the changes that have occurred, to trace out the numerous branches and canals which watered the ancient country of Babylon. This great river moved slowly through a great part of its course, and was ill adapted for navigation, as some parts of it were shoal and others rocky. Thevenot, however, is of opinion, that the Euphrates might, with little trouble, be made navigable, even by great barks, quite to the Tigris, only by clearing the channel of the stones with which it is choked in some places. The ancient mode of navigating this river was very extraordinary. The vessels were round, without distinction of head or stern, and no better than great wicker baskets, covered over with hides, guided by two oars or paddles. They were capable of carrying a very considerable weight; and when they had unloaded their cargo at Babylon, they were sold, but the hides were kept: and loading their asses with them, the navigators returned home by land, the rapidity of the stream not allowing them to return by water.

EUPHRATES, in *Modern Geography*, a river of Asiatic Turkey, which rises from the mountains of Armenia, as some have said, in two streams, a few miles to the N.E. of Erzeron, the streams uniting to the S.W. near that city; and chiefly pursuing a S.W. direction to Semisat, where it would fall into the Mediterranean, if not prevented by a high range of mountains. In this part of its course the Euphrates is joined by the Morad, a stream almost doubling in length that of Euphrates, so that the latter river might more justly be said to spring from mount Ararat, about 160 British miles to the east of the imputed source. At Semisat, the ancient Samofata, this noble river assumes a southerly direction; then runs an extensive course to the S.E., and after receiving the Tigris, falls by two or three mouths into the gulf of Persia, about 50 miles S.E. of Basfora. N. lat. 29° 50'. E. long. 66° 55'. The comparative course of the Euphrates may be estimated at about 1400 British miles. This river is navigable for a considerable distance from the sea. This river in its course separates Aladulia from Armenia, Syria from Diarbekir, and Diarbekir from Arabia, and passing through the Arabian Irak, there joins the Tigris.

EUPHRATES, a river of Africa, in the country of Whidah, on the Slave coast.

EUPHROSYNE, in *Mythology*, one of the three Graces. See GRACES.

EUPHROSYNUM, in *Botany*, a name used by Pliny and some others for the common borragé. See BORRAGE.

EUPILIS, in *Ancient Geography*, *Puffiano*, a lake of Italy, in Gallia Cisalpina, whence, according to Pliny, issued the river Lambrus.

EUPNCEA, of *eu*, *well*, and *πνεω*, *I breathe*, in *Medicine*, is a right and natural respiration.

EUPOLIS, in *Biography*, an Athenian who flourished B.C. 440, was known as a comic writer, and one of that class who marked out by name the objects of their satire, which rendered him extremely popular with the many, as he was dreaded by the great. He is mentioned by Horace and Quintilian, who put him in the same class with Cratinus and Aristophanes. His comedies were of a political cast, in one of which Alcibiades was so severely attacked, that he is said to have hired assassins to throw him into the sea. The plot did not succeed, for Eupolis wrote several comedies after the period assigned to this fact, and Ælian relates that

that he died at Ægina. Fragments of his works have come down to us, and titles of twenty of his plays. Gen. Biogr.

**EUPORIA**, in *Ancient Geography*, a town of Macedonia, placed by Ptolemy in Bifaltia.

**EUPORIA**, of *eu* and *πορος*, *passage*, in *Medicine*, is an easy preparation of medicines, or the easiness of their operation.

**EUPSYCHIANS**. See **EUNOMIOEUPSYCHIANS**.

**EURA**, in *Geography*, a town of Sweden, in the government of Abo; 17 miles N.E. of Abo.

**EVRA**, a town of Abyssinia; 12 miles S.E. of Siré.

**EVRA**, a town of Sweden, in the government of Abo; 17 miles S. of Biorneborg.

**EVREN**, a town of France, in the department of the North Coasts, and chief place of a canton in the district of Dinan, four miles S. of it. The place contains 3573, and the canton 9175 inhabitants, on a territorial extent of 117½ kilometres and seven communes.

**EURAN ISLANDS**, a cluster of small islands, on the east side of the gulf of Bothnia. N. lat. 63° 54'. E. long. 22° 39'.

**EURANIUM**, in *Ancient Geography*, a town of Asia Minor, in Caria.

**EURE**, in *Geography*, a river of France, which has its source in the forest of Logny, and terminates in the Seine, above Pont de l'Arche. Its course is northward, and extends 36 leagues.

**EURE**, formerly *Ouche*, a department of the second or northern region of France, in 49° N. latitude, bounded on the north by the department of the Lower Seine, on the east by that of the Oise, on the south by the departments of the Eure and Loire and the Orne, and on the west by the department of the Calvados. It takes its name from the river Eure, which traverses it; and its capital is Evreux. It contains 307 square leagues, and 415,574 inhabitants in five districts, *viz.* Pontaudemer, Louviers, Les Andelys, Evreux, and Bernay, 35 cantons, and 843 communes. Its fertile soil yields grain, hemp, flax, and pastures; and it has considerable forests.

**EURE and Loire**, a department of the second or northern region of France, in 48° 15' N. lat. composed of a part of *Beauce* and of *Perche*, bounded on the N.W. by the department of the Eure, on the east by the departments of the Seine and Oise and the Loiret, on the south by the departments of the Cher and Loiret, and on the west by the departments of the Orne and Sarthe. It takes its name from the rivers Loire and Eure, which water it; and its capital is Chartres. It contains 300 square leagues, and 259,967 inhabitants. It is divided into four districts, *viz.* Nogent-le-Rotrou, Chartres, Chateaudun, and Dreux; 23 cantons, and 460 communes. This department, on account of its great fertility, is called the granary of Paris, and it abounds in fruits and rich pastures.

**EVRE**, or **YEVRE**, a river of France, which discharges itself into the Cher by two streams, one near Vierfon, the other at Bourges.

**EVRECY**, a town of France, in the department of the Calvados, and chief place of a canton in the district of Caen; seven miles S.W. of Caen. The place contains 850, and the canton 13,110 inhabitants, on a territorial extent of 145 kilometres, and 29 communes.

**EVREGNIES**, a town of France, in the department of Jemmappe; nine miles N.N.W. of Tournay.

**EUREOS**, in *Natural History*, the name of a stone, described by Pliny, and seeming plainly to be the same with the *zeolithus*, which he mentions in another place, and to

be the stone now called *lapis Judaicus*; and known at this time to be the petrified spine of a sort of *echinus marinus*, or sea urchin.

**EVREUX, MEDIOLANUM, Eborice, or Civitas Eboracorum**, in *Geography*, a town of France, in the department of the Eure, of which it is the capital, and chief place of a district. Its north division contains 4200, and the canton 10,458 inhabitants, and the south division 4226, and its canton 10,853 inhabitants; the territorial extent comprehends 345 kilometres, and each division includes 30 communes. Before the revolution this was the see of a bishop, suffragan of Rouen; containing nine parish churches, two abbeys, and ten convents. This is an ancient and considerable town, with large suburbs, situated in a deep and fruitful vale on the river Eton, 23 miles N.W. from Paris. Its cathedral is a fine Gothic structure. The manufactures of Evreux consist of woollen and linen cloth, and its trade of rice, grain, wine, and cyder; but they are not considerable. N. lat. 49° 2'. E. long. 1° 15'.

**EURIA**, in *Ancient Geography*, a town of Greece, in Epirus.

**EURIPIDES**, in *Biography*, the contemporary and rival of Sophocles, and one of the most ancient Greek tragedians, was born in the isle of Salamis, in the first year of the 75th olympiad, B.C. 480, according to many writers, though the Arundelian marble places his birth five years earlier. His father's name was Mnesarchus, an Athenian, and that of his mother was Clito, a feller of herbs, according to the report of Aristophanes, the avowed enemy of Euripides; but by the testimony of later grammarians, founded on the authority of Philochorus, an ancient writer, she was of noble descent. Before the birth of his son, Mnesarchus is said to have consulted the oracle of Apollo concerning his future destiny, and to have received for answer, "that the child who should be born to him would reach the summit of glory, and gain the honour of the sacred garland," which was understood to signify the crown of victory at the olympic games. When Greece was invaded by Xerxes, Mnesarchus and his wife retired for safety, among other Athenians, to the island of Salamis. In the autumn of the year 480 B.C. when this invasion took place, the fate of Greece was in a great measure decided by the naval victory of Salamis over the Persians; and on the same day, it is said, Euripides was born, who in memory of this battle, fought in the narrow channel, or *Euripus*, which divides Salamis from the continent, received his name. Euripides, at subsequent periods of his life, was accustomed to frequent the island of his nativity, where was shewn a cave, in which some of his tragedies are said to have been composed. Euripides, in conformity to the suggestion of the oracle, and also to the custom of the country, qualified himself for honourable and successful contest at the public games, by an early initiation in the usual gymnastic exercises; but his views were directed to nobler pursuits. Accordingly, whilst he paid some attention to the art of painting, he studied rhetoric under Prodicus, celebrated for the allegory of the choice of Hercules, preserved by Xenophon, and received instructions in physics from Anaxagoras, and in morals from Socrates. In his 18th year he first applied himself to the composition of tragedies, the number of which, during the course of his life, amounted, as some say, to 75, but according to others, to 92. He does not appear, however, to have been very successful in his exhibitions on the theatre, for no more than five of his performances gained the prize at the olympic games; but they were privately read with avidity and highly applauded by his countrymen. To this purpose we may mention the following fact. After the

unfortunate expedition of the Athenians against Syracuse, several captives were kindly treated by the Sicilians, and obtained relief from indigence and wretchedness, by going about from place to place, reciting and singing the verses of Euripides. Upon their return to their own country, the poet received their personal acknowledgments. Socrates was the friend of Euripides, and is said to have given him advice and assistance in the composition of some of his dramas; and he occasionally attended the public exhibition of them. In the character of Palamedes the poet was supposed to have delineated that of Socrates; and some verses are quoted addressing the Greeks as having slain the best and wisest of their nation, which the audience applied to the fate of this philosopher, bursting into tears at the recollection of their crime. As Socrates had become an object of public persecution and calumny before the representation of the Palamedes, some application of the character to his circumstances might probably have been intended by the poet. But his death could only be alluded to by way of probable anticipation, as he survived Euripides some years. The remarkable effect ascribed to the passage of the Palamedes just mentioned might possibly have taken place at some representation of that play subsequent to the death of Socrates. Euripides was the constant rival of Sophocles, and their mutual jealousy seems to have degenerated into declared enmity. Our poet was frequently the object of raillery to Aristophanes. Euripides was twice married; but as he was disappointed in his expectation of domestic happiness, he is said to have indulged a kind of antipathy to women, for which this circumstance has been pleaded as an apology. Hence he obtained the name of *Μισογυνής*, woman-hater, though his editor, Barnes, strenuously defends him from the charge implied in this appellation, observing, that if he has described some females with all the vices incident to human nature, yet he has delineated many others with all the virtues that can adorn their sex; and Sophocles is said to have observed, that the hatred which he expressed against women was confined to the stage. In advanced life he enjoyed so little felicity at Athens, that he accepted an invitation to the court of Archelaus, king of Macedonia, where he was honourably treated, though he did not altogether escape the effects of malicious jealousy. To the consequence of a quarrel from this cause some have ascribed his tragical death; for as he was walking in a wood, the king's hounds were let loose upon him, and tore him in pieces. Others say that his death was owing to natural decay. He died at the age of about 75 years. The Athenians sent ambassadors to Macedonia, to request the removal of his body to his native country; but Archelaus refusing to comply with their request, caused him to be interred with great magnificence, and erected in honour of him a noble monument in the vicinity of Pella, his chief city. The Athenians appointed a public mourning on occasion of his death, and erected in memory of him a cenotaph on the road leading from the city to the Piræus. The following epitaph is ascribed to Thucydides, the historian.

“Μνημα μὲν Ἑλλάς ἄστια· Ἐυριπίδων· οὐρα δὲ σχη  
Γῆ Μακεδῶν, ἣ γὰρ δεξάλο τετρα βίου.  
Παῖς δ’ Ἑλλάδος Ἑλλάς Ἀθῆναι· πλεῖστα δὲ Μουσῆς  
Τετράς, ἐκ πολλῶν καὶ τοῦ ἑταίου ἔχει.”

“All Greece is the monument of Euripides; the Macedonian land possesses his bones, for there he reached the boundary of his life. His country is Athens, the Greece of Greece; having afforded general delight by his muse, he enjoys the recompence of general praise.”

It has been recorded to the reproach of Euripides, that

many of the maxims which he attributes to his dramatic characters are favourable to vice; and though he cannot be wholly exculpated from this charge, he abounds with moral maxims, expressed in noble and elegant language, which deeply impress the mind of the reader. He has been also charged with moroseness of temper; but however this be, he introduces numerous passages of tender and delicate pathos. As a tragedian, when compared with Sophocles, it seems to be the general opinion, that with less pomp of diction, less force and elevation of character, and less knowledge of dramatic effect than his rival, he more excels in tenderness, suavity, and moral sentiment. Aristotle calls him the “most tragical” of all the poets, meaning either that he was the most skilful in the drama, or the most pathetic. Euripides, it should be recollected, was the favourite poet of Milton. Possessing a high notion of the preceptive office of the theatre, he was once desired by the auditors to retrench a passage in one of his plays, but he stepped forward and said, “I do not write in order to learn from you, but to teach you.” Of his works nineteen complete plays, and the commencement of a twentieth, are still remaining. Of these, both singly and collectively, there are several editions. The best of the whole works are those of Basil, 1551, of Plantin, 1571, of Commelin, 1597, of Paul Stephens, 1604, 1611, of Barnes, *Camb.* 1694, and of Musgrave, *Oxf.* 1778. Bayle. Moreri. Barnes. Gen. Biog.

EURIPUS, *Εὐρίπος*, in *Hydrography*, properly signifies a certain strait of the sea which divides Eubœa from Attica, Bœotia, and Locris, where the currents are so strong that the sea is said to ebb and flow seven times a day; in which place, as the story commonly goes, Aristotle drowned himself out of chagrin, for not being able to account for so unusual a motion. This strait was so narrow over-against Chalcis as scarcely to admit a galley. It is now called the gulf of Negropont.

Euripus has since become a general name for all straits, where the water is in great motion and agitation.

The ancient circuses had their Euripi, which were no other than pits or ditches, on each side of the course, into which it was very dangerous falling with their horses and chariots as they ran races. The term Euripus was more particularly applied by the Romans to three canals or ditches which encompassed the circus on three sides, and which were filled occasionally, to represent naumachic or sea-battles.

The same people called their smaller fountains or canals in their gardens Euripuses; and their largest, as cascades, &c. *Niles*.

EUROCLYDON, of *Εὐρος*, east-wind, and *κλύδων*, wave, is a species of wind, of which we have an account only in Acts, xvii. 14. and concerning the nature of which critics have been much divided. Bochart, Grotius, Bentley, and others, substitute another reading, supported by the Alexandrian MS. and the Vulgate, viz. *Εὐρακίλων*, or *Euroaquilo*; but Mr. Bryant defends the common reading, and considers the Euroclydon, i. e. *Εὐρος κλύδων*, as an east-wind that causes a deep sea or vast inundation. He maintains, in opposition to Dr. Bentley's reasoning, who supposes that the mariners in the ship, the voyage of which is recited in this passage, were Romans, that they were Greeks of Alexandria, and that the ship was an Alexandrine ship, employed in the traffic of carrying corn to Italy; and therefore, that the mariners had a name in their own language for the particular typhonic or stormy wind here mentioned. He also shews from the passage itself, that the tempestuous wind called Euroclydon, beat (*κατ' αὐτῆς*) upon the island of Crete; and therefore, as this is a relative expression, referring to the

the situation of the person who speaks of it, who was at that time to the windward, or south of it, the wind blew upon shore, and must have come from the south or south-east; which, he adds, is fully warranted from the point where the ship was, and the direction it ran in afterwards, which was towards the north and north-west. Bryant's Observations, &c. 1767, p. 1. &c.

EURO-AUSTER. } See WINDS.  
EURO-Notus. }

EUROMA, in *Ancient Geography*, a town of Asia, in Phœnicia.

EUROMUS, a town of Asia, in Caria; situated E. of mount Grius, N. of mount Latmus, and N.W. of the town of Mylasa. It had a theatre and a magnificent temple.

EVRON, in *Geography*, a town of France, in the department of the Mayenne, and chief-place of a canton, in the district of Laval; 15 miles E.N.E. of Laval. This place contains 4044 and the canton 13,213 inhabitants, on a territorial extent of 205 kilometres and 11 communes. The fairs of this town are frequented.

EUROPA, in *Mythology*, daughter of Agenor, king of Phœnicia, by his wife Telaphassa, who was so beautiful, that, according to the fable, Jupiter is said to have fallen in love with her, and to have ordered Mercury to convey her to the sea-shore, where that god, having transformed himself into a bull, took her upon his back, and transported her into Crete. Some have explained this fable by alleging that a captain of Candia, named Taurus, carried off that princess, after he had taken the city of Tyre from Agenor; but others, with greater probability, assert, that some merchants of Crete, having arrived upon the coasts of Phœnicia, and seen the young Europa, were so much struck with her beauty, that they carried her off for their king Asterius; and as their ship bore upon the fore-castle a white bull, and that king of Crete had assumed the name of Jupiter, it was hence fabled that the god had transformed himself into a bull, in order to carry off the princess. Asterius is said to have married her, and to have had by her three sons; after which she is reported to have engaged the attachment and esteem of the Cretans to such a degree, that they worshipped her after her death as a divinity. They even instituted a feast in honour of her, which was called Hellotia. They afterwards gave her the surname of Minerva, and celebrated to her honour that festival which was consecrated to that goddess among the Cretans. Several authors have been of opinion that Europe took its name from this princess; but the learned Bochart believes that this part of the world was so denominated from the whiteness of its inhabitants. M. Gebelin, however, deduces the name of Europa from *Wrab*, signifying Occidental, and expressing its situation with regard to Asia.

EUROPA rocks, in *Geography*, rocks in the strait of Mozambique. S. lat. 21° 30'. E. long. 40° 16'.

EUROPE, one of the four grand divisions, or quarters, as they have been somewhat improperly called, of the terraqueous globe. Although Europe be less considerable in extent than Asia, or America, or even Africa, it claims on a variety of accounts our more particular attention. In modern times it has been the seat of literature and science; in this part of the globe every kind of cultivation and improvement has made the most rapid progress, and it has been distinguished, not only by the general temperature of its climate, the fertility of its soil, and the abundance of its productions for the supply of necessity and the gratification of luxury, but more especially for the wisdom, strength, and courage of its inhabitants, and for the excellence of its government, laws, and religion. The boundaries of

Europe were very inaccurately ascertained by the ancient geographers, and the name itself seems to have originated in a small district near the Hellespont. More than a third part of Europe, towards the north and east, has only been known with precision in modern times. It lies chiefly in the temperate zone, north of Africa, and north-west of Asia, between 35° 25' and 71° 23' N. lat. and between 9° 40' W. and 61° 5' E. longitude. From the Portuguese cape, denominated by our mariners the rock of Lisbon, in the west, to the Uralian mountains in the east, the length may be about 3,300 British miles; and the breadth from Cape Nord in Danish Lapland to Cape Matapan, the southern extremity of Greece, may be about 2,350. The contents in square miles have been variously estimated, but at a medium may be stated at about 2½ millions. On the south, Europe is bounded by the Mediterranean sea, on the west by the Atlantic, which contains the most remote European islands, the Azores and Iceland, Greenland being regarded as a part of North America. On the north the boundary is the Arctic ocean, comprehending the remote isles of Spitzbergen, and Novaya Zemlia, or the New Land. "Toward the east the limits, (says Mr. Pinkerton,) admit of some discussion: the Uralian mountains, a grand natural limit, not extending to the Arctic ocean, the river Kara, which flows into the sea of Karshoye, is admitted as a boundary. The Uralian limit extends to about 56° of N. latitude; to the south of which the grand confines of Europe and Asia have been sought in the petty distinctions of Russian governments. More natural limits might be obtained by tracing the river Oufa from its source, to its junction with the Belaisa. Thence along the Kama to the Volga, which would constitute a striking natural division, to the town of Sarepta; whence a short ideal line, the only one admitted in this delineation, will lead due west to the river Don, which would complete the unascertained boundary; that on the north and west of the Euxine being clear and precise."

The ancient inhabitants of Europe consisted of Celts in the west and south; Fins in the north-east; and Laps or Laplanders, resembling the Samoieds of Asia in the farthest north, who enriched their rude language by adopting that of the more civilized Fins. The ancient inhabitants, who seem to have been thinly scattered, were driven towards the west and north by the Scythians or Goths from Asia, whose descendants occupy the greater part of Europe; by the Sarmatians or Slavonic tribes, also from Asia, the ancestors of the Russians, Poles, &c. and who were accompanied by the Heruli, using what is now called the Lettic speech, to be found in Prussia, Lithuania, Samogitia, Courland, and Livonia, somewhat akin to the Slavonic language, with various shades of distinction. The colony of Iberi, northern Mauretani, passed into Spain at a very early period; and the later accession of Hungarians and Turks from Asia may likewise be commemorated. The present population of Europe is commonly estimated at 150,000,000; and though some writers have asserted that this quarter of the globe was anciently more populous than it is now, the opinion does not seem to be well founded. It will not readily be adopted by those who duly consider the number and magnitude of modern cities, towns, and villages; the abolition of feudal wars; the adoption of a mode of combat less destructive than that which formerly prevailed; the gradual extirpation of superstition, fanaticism, barbarity, and slavery; and the many extensive improvements made in agriculture, by eradicating forests, draining marshes, cultivating wastes, and opening canals of communication in the interior countries.

countries. It is generally allowed, that, notwithstanding the ravages of war, and emigrations to foreign parts, the population of most European states has been, for some time past, increasing. The prevalence of the Christian religion throughout Europe, except in some parts of Turkey, has been favourable to knowledge, industry, and civilization; and it has contributed to constitute the whole of Europe, as it were, into one republic, so that any useful discovery made in one state passes rapidly to the rest. The mutual intercourse between the different states of Europe is very much facilitated by its inland seas, as well as navigable rivers and canals. Of the inland seas the principal are the Mediterranean, the Baltic, and the White sea, which see respectively. Its other seas are the German, often styled the North sea, the Irish sea, and various parts of the Atlantic. The gulfs and bays of Europe are very numerous, among which we may reckon the following, *viz.* the Bothnian and Finland gulfs; the Murray frith, and Frith of Forth, on the east coast of Scotland; the bay of Biscay, a large inlet of the Atlantic, on the east bounded by France, and on the south by Spain; the gulfs of the Mediterranean, *viz.* that of Lyons, S. of France; that of Genoa, between Corsica and the Genoese republic; the gulf of Venice, between Italy and Greece; the gulf of Lepanto, N. of Morea; the Archipelago between Greece and Asia Minor; the sea of Marmara between Europe and Asia; and the sea of Azoph on the north coast of the Euxine. The most considerable straits are that of Waygatz at the N. E. extremity of Europe; the sound of Elsinore between the island of Zealand and Sweden; the Little Belt between Funen and Jutland; the Categat, or entrance into the Baltic; the strait of Dover, or English channel, between England and France; the Bristol channel, between England and Wales; St. George's channel, between Great Britain and Ireland; Pentland frith, between Scotland and the Orkney Isles; the strait of Gibraltar, between Spain and Africa; the strait of Messina, between Italy and Sicily; the Dardanelles strait, or south entrance into the sea of Marmara; the strait of Constantinople, that forms a communication between the sea of Marmara and the Euxine; and the strait of Caffa, between the Euxine and the sea of Azoph. The most remarkable capes are North Cape, the extreme point of Lapland; Cape Finisterre, on the N. W. coast of Spain; Cape St. Vincent, the S. W. extremity of Portugal; and Cape Matapau, the S. point of the Morea. Its principal lakes are those of Omega, Ladoga, and Peipus, in Russia; those of Geneva and Constance, S. W. and N. of Switzerland; Lago Maggiore, and others, in the northern parts of Italy. The largest rivers are the Volga, Don, and Dwina, in Russia; the Dnieper on the east border of Poland; the Danube, between Hungary and European Turkey; the Rhine and Elbe in Germany; the Rhone in France; the Po and Tyber in Italy; the Tago in Spain; the Scheldt and Meuse in the Netherlands; the Thames and Severn in England; the Tay in Scotland; the Shannon in Ireland, &c. &c. The principal chains of mountains are the Carpathian or Krapach mountains, between Poland and Hungary; the Alps, between France, Switzerland, and Italy; the Apennines, in Italy; the Pyrenées between France and Spain; and the extensive ridge that separates Norway from Sweden. The most distinguished islands are Great Britain and Ireland, the Orkney Isles, the Hebrides, Zealand, and Funen, in the Baltic; Iceland, in the North sea; and in the Mediterranean, Ivica, Majorca, Minorca, Sardinia, Corsica, Sicily, Malta, Candia, and the islands of the Archipelago.

The principal European states are the British empire, including England, Scotland, and Ireland; the states of Denmark, comprehending Denmark with the adjacent islands, Norway and Iceland; Sweden; Russia, formerly called Muscovy; Holland; France, including the Netherlands, Italian states, and other late acquisitions; Switzerland; Germany and Austria; Prussia; Bohemia and Hungary; Poland, now dismembered; Spain; Portugal; Sicily; Malta; and Turkey in Europe. See each under its appropriate title.

EUROPEAN Ocean. See OCEAN.

EUROPUS, in *Ancient Geography*, a town of Asia, in Parthia, founded, as Strabo says, by Nicator, and called by the Parthians *Arfacia*.—Also, a town of Asia, in Syria, situated on the banks of the Euphrates, E. of Hieropolis, and S. of Zeugma.—Also, a town of Asia, in Caria.—Also, a town of Macedonia.—Also, a river of Greece, in Thessaly, which rose in mount Citarius, and flowed into the Peneus.

EUROTAS, a river of Laconia, which commenced on the frontiers of Arcadia, watered Sparta, and proceeding southward, discharged itself into the Laconic gulf.—Also, a river of Greece, in Thessaly, near mount Olympus.—Also, a river of Italy, near Tarentum, the same with the river Galefus, according to Polybius.

EURUS, in *Mythology*, the genius of the south-east wind, according to the Grecian division of the compass into eight points; but according to the Roman division into four, Eurus was the intelligence that presided over the whole eastern quarter of the heavens. (See WIND.) "Eurus," says Spence, "according to the Roman poets, seems to have his character composed from the Apeliotes and Eurus of the Greeks: by one description of him he should have a look that seems delighted, and in another he is spoken of as playful and wanton. He is sometimes described as impetuous, and sometimes as disordered with the storm he has been driving along the sea. Horace gives us a picture of the former, and Valerius Flaccus of the latter. I should be apt to imagine, from some expressions in the poets, that he was sometimes represented on horseback, or perhaps in a chariot, whirling through the air; but there are so few remains of the ancient artists relating to these airy beings, that we have nothing from them to confirm any such conjecture."

EURYA, in *Botany*, supposed to be from *euvs*, broad or ample, the application of which to this plant we do not, from any part of the description or figure, perceive. Thunb. Jap. 11. Schreb. 321. Willd. Sp. Pl. v. 2. 856. Mart. Mill. Dict. v. 2. Juss. 432. Class and order, *Dodecandria Monogynia*. Nat. Ord. uncertain, Juss.

Gen. Ch. Cal. Perianth inferior, of five ovate, concave, obtuse, small leaves, with two lesser ones at its base. Cor. Petals five, roundish-ovate, concave, the size of the calyx. Nectary a glandular ring round the base of the germen. Stam. Filaments thirteen, extremely short; anthers erect, square, almost as long as the corolla. Pist. Germen superior, roundish, smooth; style awl-shaped, shorter than the stamens; stigmas three, reflexed. Peric. Capsule globose, tipped with the permanent style, smooth, of five valves and five cells, scarcely so big as a pepper-corn. Seeds several, obscurely triangular, dotted, brown, destitute of pubescence. Obs. Thunberg observed the flowers to be most frequently dioecious.

Ess. Ch. Calyx double; the inner of five equal leaves; the outer of two smaller ones. Petals five. Capsule superior, of five cells and five valves. Seeds numerous.

*E. japonica*. Thunb. Jap. 191. t. 25. (Fisakaki; Kämpf. Amœn. Exot. 778.) A Japanese shrub, common on the hills about Nagasaki, flowering in September and October, and cultivated in gardens for the sake of its elegance. It is smooth in every part. Branches slender, alternate, leafy. Leaves alternate, stalked, elliptic-lanceolate with a blunt point, serrated, compared by Kämpfer to those of tea, evergreen, yellowish beneath, an inch or two long. Flowers axillary, in pairs, stalked, small, white or reddish. Thunberg describes the fruit as above; but Kämpfer says "the berries resemble those of juniper, and are juicy, giving a stain like ultramarine, and containing from ten to twenty hardish brown seeds, crackling under the teeth." If Thunberg adverted to this description, he might perhaps deduce the generic name, though incorrectly, from *eu*, *well*, and *juvus*, a flowing of juice, or a falling of berries.

**EURYALÉ**, in *Mythology*, one of the Gorgons, daughter of Phorcys, and sister of Medusa: she was subject neither to old age nor death.

**EURYAMPUS**, in *Ancient Geography*, a town of Macedonia, in Magnesia.

**EURYANDRA**, in *Botany*, from *euvs*, broad, and *andros*, a male, because the male organs, or stamens, are dilated at the summit. Forst. Gen. t. 41. Schreb. 367. Juss. 280. See **TETRACERA**; to which genus Schreber, in his emendanda, 833, and Willdenow, Sp. Pl. v. 2. 1242, have at the recommendation of Solander referred it.

**EURYDICE**, in *Mythology*, the wife of Orpheus, who, flying from Aritæus that endeavoured to ravish her, was slain by a serpent. Her husband went down to the shades, and by the force of his music persuaded Pluto and Proserpine to give him leave to carry back his wife; which they granted, provided he did not look on her till he came to the light; but he, breaking the condition, was forced to leave her behind him.

**EURYMEDON**, in *Ancient Geography*, *Zacuth*, a river of Asia, in ancient Pamphylia, which had its source in mount Taurus, passed the town of Aspenus, and discharged itself into the sea of Pamphylia.

**EURYMENÆ**, a town of Greece, in Thessaly.

**EURYNOME**, in *Mythology*, the mother of the three Graces.

**EURYNOMIA**, *Εὐρυνομία*, in *Antiquity*, an anniversary solemnity in honour of Eurynome, by some thought to be the same with Diana, by others one of Oceanus's daughters.

**EURYPHON**, the Cnidian physician, in *Biography*, was a contemporary of Hippocrates, but probably older in years, since he is deemed the author of the Cnidian aphorisms, which are quoted by Hippocrates. These two physicians are said by Soranus to have met in consultation in the presence of king Perdiccas. Euryphon is mentioned by Plato the comedian, as having produced many scars on the skin of Cinesias, the son of Evagoras, by the employment of actual cauteries for the cure of empyema, or pulmonary consumption; a practice which Hippocrates pursued. See Le Clerc Hist. de la Med.

**EURYTHMIA**, from *eu* and *ρυθμος*, order, an old term in *Surgery*, signifying adroitness in handling instruments.

**EURYTHMY**, *Εὐρυθμία*, in *Architecture*, *Painting*, and *Sculpture*, a certain majesty, elegance, and easiness, appearing in the composition of divers members or parts of a body, building, or painting, and resulting from the fine proportions thereof.

The word is Greek, and signifies literally a consonance or fine agreement, or, as we call it, a harmony of all the parts.

being compounded of *eu*, *well*, and *ρυθμος*, rhythmus, cadence, or agreement of numbers, sounds, or the like things.

Vitruvius ranks eurythmia among the essential parts of architecture; he describes it as consisting in the beauty of the construction or assemblage of the several parts of the work, which renders its aspect or whole appearance graceful; *e. gr.* when the height corresponds to the breadth, and the breadth to the length, &c.

"From these three ideas or designs, *viz.* orthography, scenography, and profile, it is that eurythmy, majestic, and *venusta species edificii*, do result, which creates that agreeable harmony between the several dimensions, so as nothing seems disproportionate, too long for this, or too broad for that, but corresponds in a just and regular symmetry, and consent of all the parts with the whole." Evelyn's Account of Archit. &c.

**EUSCOM**, in *Geography*, a river of Canada, which runs into lake St. Clair. N. lat. 42° 45'. W. long. 82° 25'.

**EUSDALE**, or **EYSDALE**, a small island on the W. coast of Scotland, noted for its quarries of slate. N. lat. 56° 13'. W. long. 5° 48'.

**EUSEBES**, the name of a species of marble mentioned by Pliny: he has given us no description of it, but only tells us, that there was a seat made of it in the temple of Hercules at Tyre, from which the priests pretended that the gods used to arise.

**EUSEBIANS**, a denomination given to the sect of Arians, on account of the favour and countenance which Eusebius, bishop of Cæsarea, shewed and procured for them at their first rise; or rather from the protection afforded to Arius, and the adoption of his opinions by Eusebius bishop of Nicomedia. See **ARIANS**.

**EUSEBIUS**, pope, in *Biography*, a native of Greece, son of a physician, perhaps he himself at one period was a physician, succeeded Marcellus in the see of Rome. It is believed that he filled the pontificate but a very few months. He was a violent opponent to the re-admission of lapsed Christians to communion, and his conduct on this head created great dissensions at Rome, to put an end to which the emperor Maxentius banished him to Sicily. Moreri. Bower.

**EUSEBIUS**, surnamed *Pamphilus*, was born at Cæsarea in Palestine, of which he was afterwards bishop, about the year 270. Of his parents, and his instructors in early life, we have no account; nor is any thing recorded concerning his family. His talents and learning may, however, be justly appreciated by his numerous and valuable works. Having been ordained presbyter, probably, by Agapius, bishop of Cæsarea, he set up a school in that city, which produced many learned men, and whilst he was in this situation he formed an intimate acquaintance and friendship with Pamphilus, a learned presbyter of the same church, who is supposed to have afforded him much assistance in his studies. When Pamphilus was imprisoned in the year 307, Eusebius attended him to animate his fortitude and comfort him in his distress: and after the martyrdom of his friend in 309, he removed to Tyre, where he witnessed the firmness and patience with which many Christians endured the severity of persecution. From thence he went to Egypt, where the same scene was exhibited, and where he himself was imprisoned. As he did not suffer in common with others, some persons have insinuated, that he procured his liberty by sacrificing, or by some other mean compliance, unbecoming his Christian principles and profession. But Dr. Lardner has alleged several circumstances which evince this accusation to be altogether unfounded. At the close of the Dio-

of the persecution, Eusebius returned to Palestine, and succeeded Agapius, according to the more general opinion, as bishop of Cæsarea in the year 315. It is certain, however, that he was bishop of Cæsarea in the year 320 at the latest. After this period he was present at most of the synods held in that part of the world; and on all occasions distinguished himself by recommending peace and mutual forbearance. At the famous council of Nice in 325, he was placed by command of Constantine on the right hand of the throne, and opened the meeting by a panegyric address. At this council he seems to have been desirous of compromising the dispute between Arius, to whose sentiments he probably inclined, and the orthodox party; and with this view proposed a creed, which all the fathers allowed to be unexceptionable. Some of the most zealous partizans, however, suggested the propriety of introducing the word *ὁμοουσιος*, or *consubstantial*, as applicable to the Son; and the motion for this purpose was carried by a majority. Eusebius for some time demurred, alleging that the expression was unscriptural; but at length, being allowed to subscribe to the term in his own sense of it, he submitted; and the word became afterwards the test of orthodox belief, but very ineffectual for allaying the dissensions of the Christian church. In the year 330 Eusebius concurred with the council at Antioch in deposing Eustathius the bishop; but though the bishops and people concurred in electing him for this see, which was more honourable and profitable than that of Cæsarea, he peremptorily refused the acceptance of it. Although they applied to Constantine for the interposition of his authority, Eusebius wrote to the emperor, and obtained his permission to decline it, accompanied with encomiums on his moderation and disinterestedness, which he justly merited. At the council of Tyre in 335 he joined those bishops who condemned the proceedings of Athanasius, bishop of Alexandria; and he was deputed to attend the emperor, in order to justify the measures that had been adopted against that prelate. On occasion of this visit to Constantinople, he pronounced his panegyric on the emperor, and obtained singular marks of Constantine's condescension and favour. After his return to Cæsarea, the emperor kept up an epistolary correspondence with him, specimens of which are preserved in Eusebius's life of that prince. This work was written soon after the death of the emperor; nor did the bishop long survive, for he died in the year 339 or 340. Of the learning and application of Eusebius, his works afford ample evidence. "From his works it appears," says Tillemont, "that he had read all sorts of Greek authors, whether philosophers, historians, or divines, of Egypt, Phœnicia, Asia, Europe, and Africa." Eusebius had opportunities for conversing with the most learned men of his time, and he had access to the best libraries: so that from these different resources he was able to compile works of various kinds, in which he exercised a laudable caution with respect to his authorities and facts, and in which he also manifests a considerable degree of candour and impartiality. His works, however, as compositions, claim no very high commendation, as they are destitute of elegance and perspicuity. Upon the whole we may observe, that he was a good man as well as a learned scholar; zealously attached to religion, without bigotry; an enemy to ecclesiastical tyranny and discord, and always desirous of accommodating differences, and reconciling contending parties. Nevertheless Dr. Lardner mentions with disapprobation his concurrence with the Arian party in the harsh treatment given to Eustathius, bishop of Antioch, Athanasius of Alexandria, and Marcellus of Ancyra. As to his sentiments

with regard to the doctrine, warmly controverted in his time, Dr. Jortin inclines to think, that he was neither an Arian nor an Athanasian, but that he endeavoured to steer a middle course, and yet inclining more to the Arians than to the Athanasians. Dr. Lardner, with his usual caution, observes, that this is a question which cannot be easily decided.

Of the works of Eusebius we can here enumerate only the principal, referring for an account of the rest to the writers cited at the close of this article. The first that deserves mention is the "Ecclesiastical History," in ten books, published in 326, and containing the history of the Christian church from the birth of Christ to his own times. The best edition is that of Valesius, published at Cambridge by Reading in three volumes folio. This contains Eusebius's "Life of Constantine," in four books, written in 337 or 338, and other ecclesiastical historians, Socrates, Theodoret, &c. In this history we have several passages concerning the canon of scripture; in which the author treats of the order of the gospels; of the scriptures universally acknowledged, and of those that are not such; of the epistles, &c. (See CANON.) Eusebius's "Chronicle" was a work of prodigious labour and learning, and is preserved only in a Latin version of Jerome. The "Evangelical Preparation," in 15 books, and ten books of the "Evangelical Demonstration," which originally comprehended 20 books, are still extant; and contain the most learned defence of Christianity against both Jews and Pagans, transmitted to us from antiquity. A beautiful edition of these valuable works was published in Greek, by Robert Stephens, in 1544 and 1545, in 2 vols. fol., and reprinted at Paris, in 1628, in 2 vols. fol., with a Latin version of the former, and various readings from different MSS. and notes by Francis Vigerius, and Donatus's Latin version of the latter. Eusebius was also the author of a "Commentary upon the 150 Psalms," published by Montfaucon in 1705, as far as the 119th psalm: "A Commentary upon the Prophecies of Isaiah," published likewise by Montfaucon: "An Exposition of the Song of Songs," published by Meursius in 1627; "A Treatise against Hierocles" who had made a comparison of Apollonius Tyaneus with Jesus Christ, still extant in the original Greek; "Two books against Marcellus," who revived the heresy of Sabellius, and "Three books of Ecclesiastical Theology," written in 336; "An Apology for Origen," in 6 books, the joint work of Eusebius and Pamphilus, now existing in a Latin version; "Ten Evangelical Canons," or rules for harmonizing the gospels; the "Topics," in two books, being a kind of dictionary of places mentioned in the Scriptures; "A description of the Church of the Sepulchre at Jerusalem, &c." composed in 335; "An Oration in praise of Constantine," which is as much an argument for the truth of the Christian religion, as a panegyric upon the emperor, and much commended by Du Pin and Lardner; the "Life of Constantine," in 4 books, already mentioned: "Fourteen small pieces in Latin," published by James Sirmond in 1643, 8vo. and many other treatises, that are no longer extant. Fabr. Bibl. Græc. v. vi. Cave's H. L. vol. i. Lardner's Works, vol. iv. Jortin's Rem. on E. H. vol. ii.

EUSEBIUS, first of all bishop of Berytus in Phœnicia, and afterwards of Nicomedia, in Bithynia, was advanced to the see of Constantinople in 338 or 339. He was a relation of the emperor Julian, who was educated by him, and probably also of Constantine: and as he was a man not only distinguished by his abilities and learning, but favoured with free access to the court, his influence on behalf of the Arian

party,

party, to which he was attached, was always of great importance to their cause. From the protection afforded to Arius and his followers by Eusebius they were frequently denominated "Eusebians." Although he remonstrated against the proceedings of the court of Nice in 325, at which he was present, he subscribed the creed, probably with the same explanation which was given by the bishop of Cæsarea of the same name. That this was the case we may infer from the patronage which he afforded to the Arians, and which caused Constantine to depose him from his see and to send him into exile. He was afterwards, *viz.* in 328 or 329, recalled, and restored to his see, as well as to the favour of the emperor. Afterwards, when the Arian party became triumphant at the court of Constantinople, he encouraged the persecution of those who had been the persecutors of Arius. Having maintained his credit and influence with Constantine till his death, he gained in an equal, if not greater, degree, the confidence of his son Constantius; who promoted him, in 338, to the see of Constantinople. In this high station he was active in promoting the Arian interests, and in persecuting the Catholics. Soon after the council of Antioch, held in 341, probably in the same or the succeeding year, he terminated his career. Eusebius was eminent for his abilities and learning; and his friends have extolled his piety and virtue: but no sufficient apology can be offered for his intolerance. His writings were numerous, but none of them remain, except a "Letter concerning Arius and his Opinions," preserved by Theodoret. Fabr. Bibl. Græc. vol. vi. Cave's H. L. vol. i. Lardner's Works, vol. iv.

EUSEBIUS, bishop of Emesa, who flourished about the year 340, was descended of a very honourable family, and born at Edeffa in Mesopotamia, at which place he enjoyed the benefit of a learned education, and of early instruction in the sacred scriptures. He afterwards removed to Palestine, where he studied under Patrophilus of Scythopolis, and Eusebius of Cæsarea. He likewise went to Antioch, and from thence to Alexandria, in which city he studied philosophy, and then returned to Antioch. Some time after that, having refused the offer of the see of Alexandria, from which Athanasius was deposed in 341, he was appointed bishop of Emesa; where his distinguished proficiency in literature and the sciences led the ignorant populace to charge him with the practice of magical arts. Under this accusation, he was obliged to retire to Laodicea, and to seek the protection of George, bishop of that city, who was afterwards his biographer. When the prejudices of the misguided people at Emesa subsided, he returned thither, and here he spent the greater part of the remainder of his life, which terminated at Antioch about the year 360. He is generally thought to have embraced the Arian tenets: though Cave thinks that he should be ranked among the Semi-Arians. However this be, his character was held in high estimation for virtue and piety, as well as for learning and eloquence. Although he was great and good, as Sozomen says, he experienced the envy of those who are offended at other men's virtues. The emperor Constantius, however, was much pleased with him, and his attendance was always required by that prince in his expeditions against the Persians. He wrote a great number of books, which were chiefly treatises against the Jews, against the Novatians, and against the Manichæans; 10 books upon the epistle to the Galatians; and many short homilies upon the gospels. His works are in general lost. His treatise against the Jews is said to be still extant in a Greek MS. in the library at Vienna. The homilies, that have been published under his name at Paris in 1575, and at Antwerp in 1602, 8vo.

VOL. XIII.

are now allowed to be the productions of other writers. Socr. Hist. Eccl. l. iii. Cave's H. L. vol. i. Lardner's Works, vol. iv.

EUSEBIUS, bishop of Verceil, or Vercelli, in Italy, was born in Sardinia; and flourished about the year 354. In this year he was deputed by pope Liberius to plead the cause of Athanasius, after his expulsion from Alexandria, before the emperor Constantius; and in the council at Milan he was a zealous advocate for the deposed bishop, and for the Nicene creed. The Arian party, however, prevailed, and a decree was passed for condemning the conduct of Athanasius. Eusebius resisted, and for his unyielding steadiness he was banished to Scythopolis in Syria, afterwards to Cappadocia, and last of all into the Upper Thebais. The cause of orthodoxy, notwithstanding all his sufferings, found him an undaunted and persevering advocate. Upon the accession of Julian to the empire, he and other friends were allowed to return home; and during the remainder of his life he maintained his invincible attachment to the Catholic doctrine, and his zeal in promoting it. He died about the year 370, or soon after. Most of his works have been lost: but it is said that in the cathedral church at Verceil there is a MS., containing a Latin version of the four Gospels, which is inserted in the "Evangeliarium Quadruplex Latinae Versionis Antiquæ, seu veteris Italicæ," published by Joseph Bianchini, at Rome, in 1749. Cave's H. L. vol. i. Lardner's Works, vol. iv. chap. 90.

EUSEBIUS, bishop of Dorylæum in Phrygia in the fifth century, was at first an eminent advocate at Constantinople, but embracing the ecclesiastical life, he obtained the above-mentioned see, and distinguished himself by his opposition to the Eutychians. Some few of his works remain, which are of a polemical nature, and not worth mentioning. Cave's Hist. Lit. vol. i.

EUSENE, in *Ancient Geography*, a town of Asia, in Paphlagonia. Ptolemy.

EUSHAR, in *Geography*, a town of Asiatic Turkey, in Natolia; 24 miles E. of Isbarteh.

EUSHEIM, a town of Germany, in the principality of Wurzburg; 3 miles N.W. of Volckach.

EUSIMARA, in *Ancient Geography*, a town of Asia, in Melitené, a country of Cappadocia, seated on the bank of the Euphrates. Ptolemy.

EUSKIRCHEN, in *Geography*, a town of France, in the department of the Roer; 20 miles S.E. of Juliers.

EUSTACE, or EUSTATIA, an inconsiderable American island, about 20 miles in circuit, forming with a long point of land the entrance to the harbour of St. Augustine, in East Florida. It was also called Metanzas, or Slaughter, from a butchery made upon it by the Spaniards.

EUSTACHE, DAVID, in *Biography*, a French protestant minister, at Montpellier, assisted at the national synod held at London in 1659, as deputy of the province of Lower Languedoc, and was nominated by the assembly to present to the king the letter which they had addressed to him. He performed the task much to the satisfaction of those who had appointed him to the office. He was author of many theological pieces and sermons; the titles of some of the former are "Salutary Remedies against a Departure from God;" "The Triumph of Faith;" "An Answer to the Question asked of the Protestants, where was your Church before Luther;" "The Orator Tertullus convicted;" which was a reply to the harangue supposed to be made by the wise men of the pretended reformed religion to the queen Maria Theresa, upon her entrance into the kingdom, in which they declared that being informed she had expressed great concern that part of the king her husband's subjects

were heretics; they came to lessen that concern by embracing her majesty's religion, and that this they did after having been satisfied, by the testimony of their most famous authors, that one may be saved in the Romish religion. Moreri. Bayle.

**EUSTACHIAN TUBE**, in *Anatomy*, is the passage by which air is conveyed from the fauces to the tympanum of the ear, so called from an Italian anatomist. See **EAR**.

**EUSTACHIAN valve**, is a part formed in the right auricle of the heart. See **HEART**.

**EUSTACHIUS**, **BARTHOLOMEW**, in *Biography*, one of the most celebrated anatomists of the sixteenth century, was a native of a little village in Italy, called San Severino. He pursued his studies at Rome, where he first conceived a bias in favour of medicine, and especially of anatomy, which he cultivated with such success, that he was appointed to the professor's chair in that college. This is nearly the sum of our knowledge respecting the life of this celebrated man: he died at Rome in 1574. Eustachius was the author of several works, the greater part of which is lost. His treatise "De Controversiis Anatomicorum," which was one of the most considerable of his productions, is much regretted. Those of his writings, which remain, consist of his *Opuscula*, which appeared under the following titles, "Opuscula Anatomica, nempe de Renum structura, officio, et administratione: de auditus organo: officium examen: de motu capitis: de vena quæ azygos dicitur, et de alia, quæ in flexu brachii communem profundam producit: de dentibus." Venet. 1563, and again in 1674, with the notes of Pinus. An edition was also published at Leyden, 1707, under the superintendance of Boerhaave.

Eustachius was the author of several discoveries in anatomy; he was the first who described the renal capsules, and the thoracic duct; and his name, still attached to the passage leading from the throat to the internal ear, (the Eustachian tube,) announces the origin of our knowledge on that subject. A series of figures engraved on copper were mentioned in his *Opuscula* as nearly finished; but they were lost for more than 150 years, and were discovered, and published at Rome in 1714, by Lancisi, physician to pope Clement XI. in one volume folio. These plates were again published, but not well printed, at Geneva in 1717. The edition of Rome in 1728 is excellent; but the one published at the same city, 1740, by Petrioli, is less valuable. The same work was twice published at Leyden, under the direction of Albinus, viz. in 1744 and 1762.

Eustachius edited the lexicon of Erotian at Venice in 1666, under the title of "Erotiani, Græci scriptoris vetustissimi, vocum, quæ apud Hippocratem sunt, collectio, cum annotationibus Eustachii," in 4to. Eloy. Dict. Hist.

**EUSTATHIANS**, in *Ecclesiastical History*, a name given to the Catholics of Antioch in the fourth century, on occasion of their refusal to acknowledge any other bishop beside St. Eustathius, bishop of Sebaste in Armenia, deposed by the Arians.

The denomination was given them during the episcopate of Paulinus, whom the Arians substituted for St. Eustathius, about the year 330, when they began to hold their assemblies apart. About the year 350, Leontius of Phrygia, called the Eunuch, who was an Arian, and was put in the see of Antioch, desired the Eustathians to perform their service in his church; which they accepted; and the church of Antioch served indifferently thus both for the Arians and Catholics.

This, we are told, gave occasion to two institutions, which have subsisted in the church ever since; the first was

psalmody in two choirs; though Mr. Baillet thinks, that if they instituted an alternate psalmody between two choirs, it was between two Catholic choirs, and not by way of response to an Arian choir. The second was the doxology, *Glory be to the Father, and the Son, and the Holy Ghost*.

This conduct, which seemed to imply a kind of communion with the Arians, gave great offence to abundance of Catholics, who began to hold separate meetings, and thus formed the schism of Antioch. Upon this the rest, who continued to meet in the church, ceased to be called Eustathians; and that appellation became restrained to the dissenting party.

St. Flavianus, bishop of Antioch, in 381, and one of his successors Alexander, in 482, brought to pass a coalition or re-union between the Eustathians and the body of the church of Antioch, described with much solemnity by Theodoret, Eccl. lib. iii. cap. 2.

**EUSTATHIANS** were also a sect of heretics in the fourth century, denominated from their founder Eustathius, a monk so foolishly fond of his own profession, that he condemned all other conditions of life. Whether this Eustathius was the same with the bishop of Sebaste and chief of the Semi-arians, it is not easy to determine.

He excluded married people from salvation; prohibited his followers from praying in their houses, and obliged them to quit all they had as incompatible with the hopes of heaven.

He drew them out of the other assemblies of Christians to hold secret ones with him, and made them wear a particular habit; he appointed them to fast on Sundays; and taught them that the ordinary fasts of the church were needless, after they had attained to a certain degree of purity which he pretended to. He shewed great horror for chapels built in honour of martyrs, and the assemblies held therein.

Several women, seduced by his reasons, forsook their husbands, and abundance of slaves deserted their masters' houses.

He was condemned at the council of Gangra, in Paphlagonia, held between the years 326 and 341. Socr. lib. ii. cap. 43 and Sozom. lib. iv. cap. 24. Hard. Concil. Coll. tom. i. p. 530.

**EUSTATHIUS**, in *Biography*, a saint in the Greek and Roman churches, and bishop of Antioch, was translated to that see from the bishopric of Beræa, in Syria, about the year 323. He was a strenuous opponent of the Arian doctrine, and is said to have been the first ecclesiastic of consequence who wrote against it. He was distinguished by his zeal at the council of Nice in 325, and by his exertions in carrying the decisions of that council into effect. This conduct so much exasperated the Arian bishops, that they got him accused of adhering to the doctrine of Sabellius, rather than to that of the council of Nice. His enemies also suborned an infamous woman to appear before the synod of the Eastern bishops, to charge Eustathius with being father of a child which she held in her arms: other charges, equally disreputable, were made against him: of these he was declared guilty, and deposed from his pastoral office. He was afterwards banished to Trajanopolis in Thrace, where he died. Of his numerous writings we have few remains, excepting the fragments collected by Fabricius. Jerome thought highly of his talents; Sozomen commends him for his piety and eloquence, and says that his works were in high estimation in his time. By Theodoret he is called the great Eustathius: but Socrates and others speak very slightly of his talents, and Socrates says he is one of those obscure persons who had endeavoured to raise his own reputation

reputation by opposing Origen. He is generally admitted to have been the author of "A Dissertation concerning the Ventriloquist or Pythoness," mentioned in Samuel, first book, chap. xxvii. written against Origen on that subject. This was published by Alladius in Greek, with a Latin version, in 1629, and may be found in the 29th volume of the "Bibliotheca Patrum," and in the eighth volume of the "Critici Sacri." Fabr. Bib. Græc. vol. viii. Cave's H. L. vol. i. Lardner's Works, vol. iv.

EUSTATIA, or EUSTATIUS, *St.*, in *Geography*, one of the leeward Caribbee islands; which is a huge pyramidal rock rising out of the sea, about 29 miles in compass; but for its size the Dutch, by their industry, rendered it one of the most valuable of the Caribbees. The sides of the mountains are laid out in pretty settlements; but they have neither springs nor rivers. Sugar and tobacco have been the chief produce of this island, which the Dutch have cultivated even to the top of the pyramid, which terminates in a plain surrounded with woods, having a hollow in the middle that serves as a den for wild beasts. This island has afforded subsistence for five thousand white people, and fifteen thousand negroes, who rear hogs, kids, rabbits, and all kinds of poultry in such abundance, that they have been able to supply even their neighbours. It has but one landing place, which the original occupiers, finding difficult of access, fortified, so as to render it almost impregnable. Such for many years was the policy of the Dutch in the government of this island, that they have been jealous of admitting any strangers into their harbour, and kept them ignorant of its internal riches, whilst it has served as a storehouse for all European commodities. The property of it was first granted by the States-General to certain merchants of Flushing. It was first settled about the year 1600; but in the wars between the English and Dutch in 1665, the latter were dispossessed of it by an armament from Jamaica. The English were afterwards dispossessed by the combined forces of the Dutch and French; and the latter kept possession of it till it was restored to the Dutch by the treaty of Breda. Soon after the revolution, the French ejected the Dutch from this island, whence they were again driven by the English under sir Timothy Thornhill, who, with a view to the protection of the Dutch, left a small English garrison in the fort. The peace of Ryswick restored the Dutch to the entire possession of the island. In the year 1781 this island was obliged to surrender to the English under admiral Rodney, who confiscated the private property of the inhabitants under a plea that they had assisted France and the United States with naval and other stores. Before the close of the year it was retaken by the French under the command of the marquis de Bouille; but restored to the Dutch at the peace in 1783. It is distant 9 miles N. W. from St. Christopher's. N. lat. 17° 30'. W. long. 63° 8'.

EUSTATIA, is also the name of a town in the fore-mentioned island.

EUSTATIUS, in *Biography*, archbishop of Thessalonica, flourished in the 12th century, under the emperors Manuel, Alexius, and Andronicus Comnenus. He is celebrated for his great learning as a grammarian and critic, and is especially known as a commentator on Homer and Dionysius the geographer. His annotations on the former are copious, and abound in historical and philological descriptions: they were published at Rome in four volumes folio, between the years 1542 and 1550, and have been re-printed, particularly at Florence in 1730, with the notes and translations of Politi and Salvini. The commentaries on Dionysius were first printed in the Greek, by Robert Stephens in 1547, and have been several times re-printed. A Latin

version of them was given by Politi in 1742, at Geneva, in two volumes octavo. Moreri.

EUSTEPHIA, in *Botany*, *ωσφως*, wearing a beautiful crown, alluding to the coronet formed in the mouth of the flower, by the transverse segments of the stamens. Cavan. Ic. v. 3. 20. Willd. Sp. Pl. v. 2. 48. Vent. Regn. Veg. v. 2. 282. Class and order, *Hexandria Monogynia*. Nat. Ord. *Spathacea*, Linn. *Narcissi*, Juss.

Gen. Ch. *Cal.* Sheath oblong, divided to the base into four acute segments, withering. *Cor.* superior, of one petal, tubular, regular, in six deep, linear, obtuse, nearly equal segments, three of which are internal; without any appendage at the mouth. Nectary six little cavities in the base or tube of the corolla. *Stam.* Filaments six, inserted into the bottom of the corolla, just above each nectariferous pore, linear, flat, somewhat longer than the corolla, and three-cleft just where they emerge from it, the middle segment longest, erect, slender, bearing the anther, the lateral ones short, and horizontally divaricated, forming a crown in the mouth of the corolla; anthers incumbent, ovate. *Pist.* Germen inferior, turbinate, triangular; style thread-shaped, the length of the stamens; stigma swelling, undivided. *Peric.* as far as can be judged from the germen, a capsule of three cells. *Seeds* . . .

Eff. Ch. Calyx a divided sheath. Corolla superior, regular, tubular, cylindrical, in six deep segments. Nectary six pores in the base of the corolla. Filaments with two lateral points.

1. *E. coccinea*, Cavan. Ic. t. 238. Flowered in the royal garden at Madrid in May 1794, but its native country is unknown. *Root* perennial, bulbous. *Leaves* radical, several, linear, obtuse, somewhat falcated. *Stalk* solitary, above a foot high, stout, smooth, slightly compressed. *Flowers* four in a terminal umbel, drooping, scarlet, resembling those of *Cyrtanthus angustifolius*, but very distinct in their structure. *Sheath* nearly as long as the partial flower-stalks and flowers together.

EUSTOCHIUM, or EUSTOCHIA, in *Biography*, a Roman lady in the 4th century, who is highly spoken of by St. Jerome, was a descendant from the families of the Scipios and Paulus Æmilii, and rendered herself celebrated for the proficiency which she had made in literature. She was well acquainted with the Hebrew and Greek, as well as the Latin tongues, and conversant with the most important theological subjects. In the Catholic world her memory is cherished on account of her early devotedness to a religious course. She professed herself a disciple of St. Jerome, whom she followed from Rome to Cyprus, and thence to Antioch, Egypt, and numerous other places, and at length fixed her residence in a monastery at Bethlehem. Her mother Paula deserted a young family to accompany her in these excursions. Moreri.

EUSTRATIUS, a presbyter of the church of Constantinople, flourished about the year 578, and was author of "A Treatise concerning the Souls of the Dead," intended to prove that the souls of all men are active after their separation from the body, and that they act differently according to the difference of their merits. He was author also of "The Life of the Patriarch Eutychius," which appears to have been a funeral oration pronounced by Eustratius in the great church at Constantinople, a short time after the death of the subject of it.

EUSTRATIUS, archbishop of Nice in the twelfth century, is mentioned by Anna Comnena, and other Latin writers, as a person of profound learning and skill, as well in civil as ecclesiastical affairs. He was author of "A Treatise against Chrysolanus concerning the procession of the

Holy Spirit," and of other unpublished treatises. The only works of his which have been committed to the press are "Commentaries on the latter Analysis of Aristotle," published in Greek at Venice, in 1534; and "Commentaries on the Ethics of Aristotle," published likewise in Greek at the same place, 1536, and at Paris in Latin, 1543. Moreri.

**EUSTYLE**, formed of *eu*, *bene*, *well*, and *στυλος*, *column*, in *Architecture*, a kind of edifice, where the columns are placed at a most convenient distance one from another, the intercolumniations being all just two diameters and a quarter of the column, except those in the middle of the fronts, before and behind, which are three diameters distant.

The eustyle is a medium between the pycnostyle, and areostyle.

Vitruvius, lib. iii. cap. 2 observes, that the eustyle is the most approved of all the manners of intercolumniation, and that it surpasses all the rest in conveniency, beauty, and strength.

**EUTACA**, in *Geography*, a mountain of Egypt, near the Red sea; 12 miles S. of Suez.

**EUTAM**, a small island of the West Indies, near the east coast of Porto-Rico. N. lat. 18° 18'. W. long. 64° 41'.

**EUTERPE**, in *Botany*, *εὐτερπη*, *pleasing or agreeable*. Gært. v. 1. 24. t. 9. Juss. 453. Supposed by Jussieu to be the same with his *Corypha Sabal*, see our *ΚΟΡΥΦΗ*, sp. 3, which Adanson likewise made a distinct genus. If it be so, Gærtner's classical appellation may well take place of the barbarous Sabal.

**EUTERPE**, of *eu*, *well*, and *τερπη*, *I delight*, in *Mythology*, one of the nine Muses, which presided over wind-instruments: she is represented with a crown of flowers, playing on a double flute, with Cupid at her knees. Sometimes she has a mask in her left hand, and a club in her right. To her the invention of tragedy is ascribed.

**EUTHIA**, a term in the *Ancient Music*, which implies a succession of notes proceeding from grave to acute. Euthia was one of the parts of the ancient Melopœia.

**EUTHYMIA**, *Εὐθυμία*, among the Greeks, signified such a disposition or state of the mind, as could not be ruffled either by good or bad fortune, by sickness or health, good or evil. Mem. Acad. Inscript. vol. xiv. p. 131.

**EUTHYMIUS**, in *Biography*, flourished in the tenth century, first as a monk, and afterwards, by his talents and virtues, he so far recommended himself to notice, that he obtained the appointment of "Syncelle," an office of high rank under the patriarch, and he was also chosen confessor by the emperor Leo VI. In 906 the patriarch Nicholas was deposed by the emperor, and Euthymius was elevated to it in his stead. Upon the death of Leo, his successor Alexander II. re-established Nicholas in the patriarchal chair, and sentenced Euthymius to banishment, a punishment which he bore with fortitude and patience till his death; in or about the year 920. Another patriarch of Constantinople, of the name of Euthymius, obtained that dignity in the year 1410, and enjoyed it till his death in 1416. Moreri.

**EUTHYMIUS ZIGABENUS**, was a monk of the order of St. Basil, who flourished at Constantinople about the beginning of the twelfth century. By his superior talents he acquired the patronage and esteem of the emperor Alexius Comnenus, at whose command he drew up his Panoplia, or defence of the orthodox faith against all heresies. It consists chiefly of passages selected from the writings of the ancient Greek fathers on different points, in which heretics have departed from the Catholic doctrine. Euthymius was

also the author of "A Commentary upon the Psalms and Canticles," of which a Latin version was published by Saulius in 1530, and since that time more than once reprinted: "A Commentary on the four Evangelists," selected from the ancient fathers; "Commentaries on the Epistles of St. Paul;" "A Treatise against the Heresies of the Massilians, &c." Moreri.

**EUTHYPOROS**, from *εὐθύ*, *straight*, and *πορίζω*, *to pass into*, among the old terms of *Surgery*, meant extension; made in a straight line, in order to reduce fractures, and dislocation.

**EUTIN**, in *Geography*, a town of Germany, in the bishopric of Lubeck, situated by the side of a lake, the usual residence of the prince bishop, the bishopric, like that of Osnaburg, being secular; 20 miles N. of Lubeck. N. lat. 54° 10'. E. long. 10° 32'.

**EUTOCIUS**, in *Biography*, a considerable mathematician, who lived at the time of the decline of the sciences in Greece, was a native of Ascalon, in Palestine, and a disciple of Isidorus, one of the celebrated architects employed by the emperor Justinian. He probably flourished about the commencement of the sixth century, though we have no particulars respecting his life; but his works reflect much honour on his memory. He wrote elaborate and perspicuous "Commentaries on the books of Archimedes concerning the Sphere and Cylinder;" and also on the first four books of the Conics of Apollonius Pergæus. These commentaries have not only elucidated many difficult passages in those profound writers, but have tended to throw light on the history of mathematics. There have been many editions of them, but the most magnificent was that in the edition of the works of Archimedes, printed at Oxford in folio, in the year 1792, which was prepared for the press by Torelli of Verona; and that in Dr. Halley's edition of the eight books of Apollonius, published at Oxford in 1710. Moreri. Montucla.

**EUTROPIUS**, a Latin historian of the fourth century, is supposed to have been a native of Aquitain. He bore arms under Julian, in his expedition against the Persians, and is said to have risen to the senatorian rank. He wrote several works, of which the only one remaining is an abridgement of the Roman history, in ten books, from the foundation of the city to the reign of the emperor Valens. This is a neat compendium, and has long since been received as a school-book. Moreri.

**EUTROPIUS**, the eunuch minister of the emperor Arcadius, who rose by base and infamous practices from the vilest condition to the highest pitch of opulence and power, was probably a native of Asia. In the year 395 he was made great-chamberlain to Arcadius, emperor of the East. After the fall of Rufinus, he succeeded that minister in the confidence of his master, and rose to unlimited authority: All persons of whatever rank humbled themselves before the favourite, who became the capricious disposer of honours and emoluments of every kind, and in 399 he, an eunuch, even assumed the dignity of consul, a disgrace to Rome never before equalled. Honours, if such they may be denominated, of every kind were accumulated upon him: the towns were filled with his statues, and he was entitled the third founder of Constantinople. His predominant passion was the love of money, and of course the most shameful venality directed all appointments to the high offices of the state. As a security to his person, a law of treason was passed, which extended the penalties of that crime to every attempt against the ministers and servants, as well as against the person of the emperor. Such a shield was not sufficient to defend him from the influence of court intrigue. An insult

sult which he offered to the empress caused her to implore the protection of her husband, and at the same moment complaints were offered against him from other quarters, which induced the emperor to sign his condemnation, and the fallen and justly execrated favourite was obliged to seek refuge in the sanctuary of a church, from the pulpit of which Chrysostom pronounced an eloquent discourse, pointing him out to the people as an example of the instability of human grandeur. He afterwards surrendered himself on promise that his life should be spared, and was condemned to perpetual exile in Cyprus. Thither he was conveyed, but being hastily brought back and tried on another charge, he was condemned and beheaded in the year 399. Gibbon.

EUTYCHIA, in *Ancient Geography*, an island of the Ægean sea, before the Pagasai gulf.

EUTYCHIANS, in *Ecclesiastical History*, ancient heretics, who denied the duplicity of natures in Christ; thus denominated from Eutyches, the archimandrite, or abbot of a monastery at Constantinople, who began to propagate his opinion A. D. 448.

The aversion Eutyches bore to the heresy of Nestorius threw him into another extreme not less dangerous than that he so warmly opposed; though some passages in St. Cyril, which raised the unity of the person of Jesus Christ very high, contributed likewise to his delusion. At first he held that the *Logos, Word*, brought his body down with him from heaven; which was a near approach to the heresy of Apollinarius; and, though he afterwards testified the contrary, in a synod at Constantinople, wherein he was condemned, yet he could not be brought to acknowledge that the body of Jesus Christ was consubstantial with ours.

In effect, he did not seem quite steady and consistent in his sentiments; for he appeared to allow of two natures, even before the union; which was apparently a consequence he drew from the principles of the Platonic philosophy, which supposes a pre-existence of souls; accordingly he believed that the soul of Jesus Christ had been united to the divinity, before the incarnation; but then he allowed no distinction of natures in Jesus Christ since his incarnation.

See the dissertation of H. Hardouin, "De Sacramento Altaris;" wherein that Jesuit endeavours to unfold all the sentiments of the Eutychians.

This heresy was first condemned in a synod held at Constantinople, by Flavian, in 448, approved by the council of Ephesus, called *Conventus latronum*, in 449, and re-examined and fulminated, in the general council of Chalcedon, in 451. The legates of pope Leo, who assisted at it, maintained, that it was not enough to define, that there were two natures in Jesus Christ, but insisted strenuously, that, to remove all equivocations, they must add these terms, *without being changed, or confounded, or divided*.

The heresy of the Eutychians, which made a very great progress throughout the East, at length became divided into several branches. Nicephorus makes mention of no fewer than twelve; some called *schematici*, or *apparentes*, as only attributing to Jesus Christ, a phantom, or appearance of flesh; and no real flesh; others *Theodosians*, from Theodosius, bishop of Alexandria; others *Jacobites*, from one James, *Jacobus*, of Syria; which branch established itself principally in Armenia, where it still subsists. Others were called *Acephali*, q. d. *without head*; and *Severians*, from a monk called Severus, who seized on the see of Antioch in 513.

These last were subdivided into five factions, *viz. Ag-*

*noete*, who attributed some ignorance to Jesus Christ; the followers of Paul; *Μελανοι*, that is, the *black Angelites*, thus called from the place where they were assembled; lastly, *Adrites*, and *Cononites*.

EUTYCHIANS was also the name of another sect, half Arian, half Eunomian, which arose at Constantinople in the fourth century.

It being then a matter of mighty controversy among the Eunomians at Constantinople, whether or no the Son of God knew the last day and hour of the world, particularly with regard to that passage in the Gospel of St. Matthew, chap. xxiv. ver. 36. or, rather, that in St. Mark, xiii. 32. where it is expressed, that *the Son did not know it, but the Father only*; Eutychius made no scruple to maintain, even in writing, that the Son did not know it; which sentiment displeasing the leaders of the Eunomian party, he separated from them, and made a journey to Eunomius, who was then in exile.

That heretic acquiesced fully in Eutychius's doctrine, and admitted him to his communion; Eunomius dying soon after, the chief of the Eunomians at Constantinople refused to admit Eutychius; who, upon this, formed a particular sect of such as adhered to him, called *Eutychians*.

This same Eutychius, and one Theophronius, as was said in Sozomen's time, were the occasions of all the changes made by the Eunomians in the administration of baptism; which consisted, according to Nicephorus, in only using one immersion, and not doing it in the name of the Trinity, but in memory of the death of Jesus Christ.

Nicephorus calls the chief of that sect not Eutychius, but Eupychius, and his followers Eunomioeupychians.

EUTYCHIANUS, in *Biography*, bishop of Rome, succeeded to that high office on the death of Felix, in the year 275, and presided over the church about eight or nine years, when he died. Catholics have considered him as a martyr to the cause of truth; but historians, in general, infer, from the unmolested state of Christians, at that period, in Rome, that he died a natural death. There are two decretal epistles of this pope extant, relative to subjects of ecclesiastical discipline. Moreri. Bower.

EUTYCHIUS, patriarch of Constantinople, was born in the year 512. He was brought up to the ecclesiastical profession, and obtained in early life the episcopal dignity in a town of Pontus, which he afterwards relinquished, and entered into a monastery in the city of Amasæa. In 552 he was deputed by the bishop of that city to Constantinople, as his representative, in the approaching general council that was to be held there. Before the meeting of the council, he obtained the favour of Justinian, who raised him to the patriarchate of Constantinople, which became vacant in the year 553, by the death of Mennas. Almost immediately after he had assumed the new character, he presided at the council in which the opinions of Origen and his followers were condemned. Some years after, *viz.* in the year 564, Justinian endeavoured to obtain the patriarch's sanction to a doctrine which he had adopted, *viz.* that the body of Jesus Christ was rendered incorruptible before his resurrection, by the union of the divine and human natures; but when Eutychius steadily refused to countenance the opinion, the emperor deposed him from the patriarchate and sent him into exile. In 578, he was reinstated in the see of Constantinople, by the emperor Tiberius II. and he died in the year 585, at the age of 73. There is extant, in the fifth volume of the "Collectio Conciliorum," an epistle of his to pope Vigilius.

He was author of other pieces; of these a fragment of one only remains, "Concerning the Souls of the Dead." Moreri.

**EUXINE SEA**, called the *Black Sea*, as it is said, either from its black rocks, or dangerous navigation, an inland sea, situated partly in Europe, and partly in Asia; bounded on the north by the government of Caucasus and Ekatarinoflav, on the east by Mingrelia and Georgia, on the south by Natolia, and on the west by European Turkey. This sea is divided into the Euxine proper, the Pontus Euxinus, computed to be 1000 versts in length, and 500 in breadth, and the sea of Azof, (see Azof) the Palus Mæotides of the ancients, which, without including the bay of Taganroh, is stated to be 200 versts long, and 160 versts broad. Both these are now entirely within the confines of the Russian empire. The sea of Azof, called palus, or a marsh, by the ancients, because it was polluted by mud, is united to the Euxine by the straits of Caffa, or the ancient Cimmerian Bosphorus. The most important of the bays formed by these seas are the Liman, at the mouth of the Dnieper, the bay near Perekop, and that close to Yenikalé. The most considerable island belonging to these seas in the vicinity of the Russian coasts, is Taman. The principal harbours are Caffa, now Theodosia, Sebastopol, Kofkof, Balaklava, and some others. At the western extremity of these seas, within the province of Taurida, is a very large pool, called Sivash, or the Putrid sea, which is about 140 versts long, and 54 broad. The chief rivers that fall into the Euxine, are the Kuban, or Hypanis of the ancients, the Don, or ancient Tanais, the Dnieper or Borysthenes of ancient geographers, and the Bogur, which rises in Poland, parting that kingdom, and a portion of European Turkey from Russia, and at Otchakof, falls into the Euxine. The Euxine sea was formerly denominated ἀξινος, or *inhospitable*, on account of the barbarity of the inhabitants of its coasts; but when they became civilized by their commerce with the Greeks, the name was changed into ευξινος, i. e. *hospitable*, or favourable to strangers.

**EUZET**, a town of France, in the department of the Gard; nine miles W. N. W. of Uzès.

**EUZOIUS**, in *Biography*, was in early life a deacon of the church of Alexandria, from which office he was expelled by Alexander, bishop of that see, at the same time with Arius, on account of his espousing the principles of that celebrated character. They were both involved in the like condemnation at the council of Nice. About the year 355, he presented a confession of faith to the emperor Constantine, which met with the approbation of that sovereign, and which was the means of bringing him into consequence at the imperial court, when the orthodox party were thrown in the back ground. He was appointed to the see of Antioch, and called upon to baptize the emperor Constantius. His influence was now very considerable, and to this the friends of Athanasius attribute much of the persecution by which that bishop was harassed. Moreri.

**EUZOIUS**, bishop of Cæsarea, was educated in that city at the same time with Gregory Nazianzen. On the death of Acacius he obtained the bishopric of Cæsarea, after maintaining a violent contest with the different rival candidates. He was in principle an Arian, or nearly so, and on that account was deposed from his see under the reign of the emperor Theodosius, about the year 380. He was author of numerous treatises now lost; possessed with much learning, and was very diligent in the discharge of his episcopal functions; but he is principally celebrated on

account of his great exertions in promoting the interests of science and literature. He manifested much zeal in the restoration and improvement of the library at Cæsarea, which had been originally collected by Origen and Pamphilus, and was at this period fallen into decay. To this object he devoted his time and labour, taking care that faithful transcripts should be procured of such books as were in a perishing state, and increasing their numbers by new collections. Moreri.

**EWAGE**, *Ewagium*, in our *Old Writers*, the same with *aquage*, which is toll paid for water-passage. It is derived from the French *eau*, water.

**EWALD**, JOHN, in *Biography*, a Danish poet, was born at Copenhagen in the year 1743. His father was a clergyman, and when he found his own end approaching he sent his son for education to Sleswick, and died in a few hours after. Licht, the person to whose care young Ewald was entrusted, treated him in every respect as his own son, and gave him free access to his library. The books most agreeable to his taste were romances, which he read with the greatest avidity. The adventures of Tom Jones and Robinson Crusoe, particularly the latter, had made such an impression on his mind, and had excited his passions so strongly, that he eloped from Sleswick in his thirteenth year, in order to proceed to Holland, that he might undertake a voyage to Batavia, in the hope of being shipwrecked and thrown on some desert island. Scarcely had he travelled four miles, before he was overtaken by his preceptor and friend, who carried him back by force. At another time having read and heard of many romantic tales respecting saints and martyrs, he was desirous of becoming a martyr for the cause of Christianity. At length he resolved upon the profession of a soldier, which being opposed by his friends, he left home, in company with his brother, and joined the Prussian service, from this he deserted to the Austrian army, in which he was first a drummer, and then a serjeant. A commission was offered him, provided he would embrace the Catholic religion, which he absolutely refused, and in a short time deserted again. On his return to Denmark he devoted himself to theology, and studied with so much diligence as to be fit for examination in the course of a year. He had paid his addresses to a lady, who, suspecting him not to be in earnest, gave her hand to another: this to affected Ewald as to produce a complete change in his disposition, and to give his ideas a melancholy cast. He now abandoned himself to pleasure, and injured his constitution. To give vent to the effusions of his mind, he wrote a piece, called "The Temple of Good Fortune," which proved the source of all his future fame. It obtained the approbation of the society of Belles-lettres; and procured him the friendship of M. Carlens, a zealous votary of the muses, which he enjoyed, without interruption, during the remainder of his life. On the death of Frederic V. in 1766, he composed an elegy, which was received with universal approbation, and Ewald, intoxicated with the praises bestowed upon his work, began to consider himself one of the greatest poets that Denmark had ever produced. The society of Belles-lettres proposed as the subject of a prize the best ode on any of the attributes of the deity, and Ewald, determined to try his fortune, made choice of the divine goodness, and had already formed his plan, when he learned that Benzon, one of his most intimate friends, was employed on the same subject. Unwilling to enter the contest with a friend he abandoned his subject, and wrote his Adam and Eve, a sort of half drama, in one act, which possessed much merit, but without order or any regard to the laws of composition. He hoped that this might obtain the prize, but was disappointed, and began to study poetry, being now resolved to read; and

not to write any more for two years. The works of Corneille and Klopstock fell into his hands, and gave his taste a new direction. His next work was "Rolfé Krage," a tragedy in the style of Ossian, and "The songs of Skalden," which he wrote under the eye of Klopstock, who had a very great and sincere affection for him. During the time he was employed on this piece, he was attacked by a disease, under which he languished for ten years. It proceeded from the gout, and was often attended with excruciating pain, yet his spirits and cheerfulness rarely forsook him, and he wrote in the intervals of his ease some small theatrical pieces, which in part related to present times and manners, and which abounded with humour and the keenest satire. Ewald had obtained from the king a pension of a hundred dollars, but this being insufficient for his maintenance, he was obliged, by writing temporary poems, to gain a part of his livelihood, till the profits arising from the representation of his theatrical pieces, and from the sale of his works, should place him beyond the fear of want. He died at Copenhagen in March 1781, in the thirty-eighth year of his age. In strength of imagination, spirit and originality, Ewald surpasses all the other Danish poets. His excellent qualities gained him the affection of those who knew him. He never prostituted his muse to improper purposes, and never, says his biographer, did an immoral or pernicious line flow from his pen. A complete edition of his works was published at Copenhagen between the year 1781—1791. Gen. Biog.

EWANICZOW, in *Geography*, a town of Poland, in the palatinate of Kaminiéc; 64 miles N.N.W. of Kaminiéc.

EWANO, a town of Poland, in Galicia; 36 miles S.E. of Halicz.

EWE, a small island on the W. coast of Scotland, at the entrance of Loch Ewe. N. lat.  $57^{\circ} 53'$ . W. long.  $5^{\circ} 37'$ .

EWE, in *Rural Economy*, the female of the sheep kind of animals. It is of very great importance in the forming of this sort of stock to have good ewes. (See SHEEP.) It is the practice in some of the more northern districts to have recourse to the milking of the ewes in order to make cheese from it. But it is said to have been lately found so injurious to the animals, and to be attended with so little profit, that it is, at present, much on the decline.

EWE-Cheese, is that sort of cheese which is prepared from the milk of the ewe. It is a very strong pungent kind of cheese, which is not well relished by many. Some, however, consider it as very rich and excellent, preferring it to the other sorts of cheese. In some places these cheeses are made of a considerable size, perhaps, nearly as large as those of the Cheshire dairies, one, two, or three hundred ewes being milked regularly for the purpose. See CHEESE.

EWELL, in *Geography*, is a market town in the hundred of Copthorne, and county of Surry, situated at the foot of Banstead downs, distant S.E. by E. of London 13 miles. The weekly market is held on Thursdays, and it has two annual fairs, one the 12th of May, the other the 29th of October. The number of houses, according to the returns in 1801, is 194, and of inhabitants 1112. Here is the head of an extraordinary spring, which forms a curious natural jet d'eau, breaking out in several places. After watering Epfom-court meadows it flows in a fine stream called the Malden, and falls into the river Thames at Kingston.

Near this town stood the magnificent palace, from its grandeur and splendid decorations, denominated "None-Such," erected by king Henry the Eighth. Charles the Second having conferred it upon his favourite mistress, the infamous duchess of Cleveland, she caused it to be taken down, and sold the materials.

EWENNY, a river which has its source in the mountains to the north of Peterston super montem, and passing by Coychurch and Eweny priory, joins the river Ogmoré near Merthyr Mawr, below which it falls into the Bristol channel. A phenomenon on this stream has given rise to a geological error, which has generally been credited with ut proper investigation, that the river makes a "dip under a mountain, appearing again near Nevera bridge, after a subterraneous passage of two miles." "Mr. Lethieuller observes, "that between Merthyr Mawr, near which also were deep sands, and New-inn bridge, the river Ogmoré, or rather a branch of it, runs a quarter of a mile under the hill, passing also under several natural bridges; after which, issuing out with great violence, it joins the main stream. The maps again here mistake in giving this river the name of Ogmoré before its junction with the Eweny, after which only it assumes that name, being called before the Bridgend river, as it comes from Bridgend, where it runs under ground a little to the north of that place, and appears again from under Ogmoré hill." See *Archæologia*, vol. iv. p. 27. It occurs near the junction of the Eweny with the river Ogmoré. From the foot of a long ridge of down, where the hill makes a bold escarpement to the vale, issues a large body of water, exceeding the quantity previously flowing down the river, except after rains. In its passage from under the hill it is heard to boil and rage, and rushes out with foaming impetuosity, as though it had met with violent interruption in its course; and forms two streams, which immediately appear different in the velocity of their motions and quality of their contents; one being what is vulgarly called *hard*, and the other *soft* water. The stream to the southward is sought for culinary, and that to the northward for lavatory purposes. In trying it, Mr. Evans observes, "the water from the opposite sides of the stream had a different effect upon the tongue and palate, and by a brief analysis it was discovered, that the one contained a portion of calcareous matter in solution; and the other left but little residue, which was of an argillaceous nature." An attempt was then made to ascertain whether the river might not enter some other part of the hill, and by a subterraneous passage here seek daylight again, as is reported of the Deveril in Wiltshire, and the Mole in Surry. But after a fruitless search the smallest vestige of such a subterraneous course could not be traced. The phenomenon therefore in question appears to proceed from two powerful springs, rising in the internal parts of the hill, the streams of which having flowed separately, here unite, but without intermingling their waters, till they join the Eweny. Evans's Tour in South Wales.

EWENNY Priory, in *Antiquity*, was a monastery of the Benedictine order, founded by John Maurice de Lumbres, Lord of Ogmoré, A. D. 1140; and given as a cell to Gloucester Abbey. Its revenues, as valued at the dissolution, were 78*l.* 0*s.* 8*d.* It stands close to the road leading from Newton to Pyle in Glamorganshire, South Wales, in a marshy plain, near the banks of the river Eweny. It was surrounded by strong embattled walls, having two gateways; and the one forming the principal entrance had two portcullises: these, with parts of massive towers visible among its ruins, indicate it was intended as a place of security, as well as religious retirement. The buildings appear to have been very extensive, and some rooms, which formed the abbót's lodge yet remaining, are large and stately; particularly the great hall or refectory. But the abbey church, still standing, is a noble edifice, the simple and uniform architecture of which must be gratifying to every admirer of the arts. It is a massive building of a cruciform shape, consist-

ing of a nave, two transepts, and a choir; in which heavy circular arches rest upon round bulky columns with simple capitals: the windows also and door-ways have all the circular arch, which have induced some to refer it to a Saxon period. The whole certainly denotes the earliest Norman style of architecture. The curious stone vaulted groined roof of the choir claims particular attention; and the neglected effigies of the founder, bearing this inscription, "Ici gist Morice de Lundres le fundur, Deu li rende sun labur. Am." In the south transept lies another rude stone figure of a knight in armour, which has generally been thought commemorative of Pain de Tuberville lord of Coity. But sir Richard Hoare has shewn this statement, which originated with Camden, to be erroneous. After having the tomb cleaned, he was enabled to read the inscription thus,

"Sire Roger de Remi gist ici  
Deu de son alme eit merci am."

The person here named "De Remi," sir Richard supposes to have been some friend, and follower of Morice de Lundres. The floor of the church has been paved with glazed porcelain tiles, ornamented with various devices, such as are seen in other buildings of a similar nature; but few now remain. The nave is at present used as the parish church for divine worship, and the choir has a cemetery for distinguished families in the vicinity: monuments for whom, particularly that of Carne, adorn its walls. It must be matter of regret to those interested in ancient buildings, to see the present dilapidated state of this once noble structure: in many places roofless, the windows unglazed, the roof of the choir cracked, the sepulchral monuments broken, and thrown carelessly about; and this noble sanctuary, which has stood near seven hundred years, and exhibits the most perfect specimen of early Norman architecture of any church in the kingdom, rapidly approaching to its dissolution. Evans's Tour in South Wales, and the Translation of Gyraldus's Itinerarium by sir Richard Colt Hoare.

EWER, in *Rural Economy*, a term sometimes provincially applied to the udder of the cow, or other animal. See UDDER.

EWES, or EUS, in *Geography*, a river of Scotland, which joins the Esk at Langholm, in Dumfries-shire; and the valley through which it passes is called Ewesdale.

EWRY, an office in the king's household, where they take care of the linen for the king's table; lay the cloth, and serve up water in silver ewers after dinner, whence the office takes its name.

EXACERBATION, in *Medicine*, signifies the increase or return of the symptoms in those fevers of the remittent, intermittent, or even continued class, in which the febrile condition is renewed at regular periods, or becomes augmented. It is nearly synonymous with *Paroxysm*; but is more particularly restricted to the periodical increase of the remittent, or continued fevers, in which there is no absolute cessation of the febrile state. The evening exacerbation of hectic fever is a familiar example. Dr. Cullen asserts his belief, that there are commonly two exacerbations and remissions both of hectic and of continued fever in the day; the one in the forenoon, the other in the evening: that of the morning, however, if it really occurs, is less distinct, and many practitioners have been unable to detect it. See FEVER, and HECTIC.

EXACHORD. See HEXACHORD.

EXACHORDE, *Fr.* ESSACORDO, *Ital.*, an instrument with six strings, or a system composed of six sounds, such as the hexachord of Guido, which see.

EXACTION, in *Law*, a wrong done by an officer, or

one pretending to have authority: in taking a reward, or fee, for that in which the law allows not of any.

The difference between exaction and extortion, consists in this; that extortion is, where the officer takes more than his due; and exaction, where he wrests a fee, or reward, where none is due.

EXACTIS, in *Natural History*, a name given by Linnæus, and some other authors, to a species of star-fish, of the more branched kind, whose rays are six in number, when they first part from the body, but very soon branch out into a great number more. See STAR-fish.

EXACTOR REGIS, in *Law*, the king's exactor, or collector. Sometimes it is taken for the sheriff. But generally, "quicumque publicas pecunias, tributa, vestigalia & res fisco debitas exigit, proprie nominatur exactor regis."

EXACUM, in *Botany*, a name which Pliny says has been given to the Lesser Centaury, because it carries off all bad medicines by stool, apparently from *εξ*, out of, and *ακρωτα*, to drive, or force onward. Linn. Gen. 57. Schreb. 77. Willd. Sp. Pl. v. 1. 634. Sm. Fl. Brit. 182. Mart. Mill. Dict. v. 2. Juss. 142. Gærtn. t. 114. Class and order, *Tetrandria Monogynia*. Nat. Ord. *Rutaceæ*, Linn. *Gentiana*, Juss.

Gen. Ch. Cal. Perianth inferior, in four deep, ovate, slightly spreading, permanent segments. Cor. of one petal, permanent, salver-shaped; tube inflated, the length of the calyx; limb in four deep, roundish, spreading lobes. Stam. Filaments four, thread-shaped, inserted into the tube, not so long as the limb; anthers roundish. Pist. Germen superior, oval, filling the tube; style thread-shaped, rather oblique, the length of the stamens; stigma capitate. Peric. Capsule elliptical, as long as the calyx, compressed, with a longitudinal furrow at each side, of two cells, bursting at the top. Seeds numerous, small, roundish, affixed to a central receptacle which forms the partition of the capsule.

Ess. Ch. Calyx in four segments. Corolla salver-shaped, with an inflated tube. Capsule superior, with two furrows, two cells, and many seeds, bursting at the top. Stigma capitate.

Obs. The flowers in some species are five-cleft, with a correspondent number of stamens.

Since this genus was founded by Linnæus on the examination of some dried East Indian specimens of his *E. sessile* and *pedunculatum*, Sp. Pl. 163, several species have been added to it by different botanists, either entire new discoveries, or separated from the old genus of *Gentiana*. Vahl has also referred hither the *Coutoubeæ* of Aublet, Guian. t. 27, 28, with unquestionable propriety, though Jussieu and Schreber have kept it separate, the latter by the name of *Picrium*, alluding to its bitterness.

Our only British species is *E. filiforme*, Engl. Bot. t. 235, found in spongy or sandy bogs, in Dorsetshire, Devonshire; and Cornwall, flowering in July. This is a small, slender, inconspicuous annual, with a branched stem; opposite, sessile, lanceolate leaves; and small, terminal, solitary, yellow flowers, expanded only while the sun shines bright upon them. It was the *Gentiana filiformis* of Linnæus and all following authors, till referred to *Exacum* in Engl. Bot.

*E. viscosum*. Sm. Ic. Pi&t. t. 18. (*Gentiana viscosa*; Ait. Hort. Kew. v. 1. 321.) has pentandrous five-cleft flowers. This is a handsome green-house plant, brought from the Canary islands by Mr. Masson. The stem is shrubby, three feet high, with oblong ribbed leaves, and large terminal panicles of yellow flowers.

The annual species are scarcely to be cultivated, no succulent

cessful method of raising them from seed in a garden having yet been discovered.

**EXÆRESIS**, from *εξ*, *out of*, and *αιρειναι*, *to remove*, in *Surgery*, was divided by the ancients into six branches, namely, lynchæsis, diæresis, exæresis, apheræsis, prosthesis, and diorthrosis. Exæresis implied all such methods and operations, as had for their object the removal of diseased, redundant, or extraneous substances from the body.

**EXAGGERATION**, in *Rhetoric*, a figure whereby we enlarge or heighten things; making them appear more than they really are, whether as to goodness, badness, or other qualities.

The word is formed of the Latin *exaggero*, *I exaggerate*; which is a compound of *ex* and *agger*, *a mound*, or *elevation of earth*. See **HYPERBOLE**.

**EXAGGERATION**, in *Painting*, is a method of representing things, wherein they are loaded too much, or marked too strongly; whether in respect of the design, or the colouring, or the position of the object.

Exaggerating differs from caricaturing, in that the latter perverts, or gives a turn to the features, &c. of a face which they had not; whereas the former only improves, or heightens what they had.

The latter is a kind of burlesque on the object, and is generally meant to ridicule: the former is usually an exalting or enlivening of the beauties of the object, beyond what nature allows. The painter is obliged to have recourse to an exaggeration of colours, both on account of the surface of his ground, the distance of his work, and of time, and the air, which diminish and weaken the force of the colours; but this exaggeration must be conducted in such a manner, as not to put the objects out of their natural characters. The term exaggeration is not now in use. See **STYLE** in *Painting*.

**EXAGON**. See **HEXAGON**.

**EXALMA**, from *εξαλλω*, *to leap out*, in *Surgery*, a dislocation of the vertebrae, according to Hippocrates.

**EXALTACION**, in *Geography*, a town of South America, in the government of Moyes; 50 miles S. of Trinidad.

**EXALTATION of the Cross**. See **Exaltation of the Cross**.

**EXALTATION**, **ELEVATION**, is chiefly used in a figurative sense, for the raising or advancing a person to some ecclesiastical dignity; and particularly to the papacy.

The term exaltation is, in some measure, appropriated to the pope; and expresses his inauguration, coronation, taking possession, and the beginning of his pontificate.

We shall here add, that the cross was delivered up by a treaty of peace made with Siroes, Chosroes' son. The institution of this treaty is commonly said to have been signalized by a miracle; in that Heraclius could not stir out of Jerusalem with the cross, while he had the imperial vestments on, enriched with gold, and precious stones; but bore it with ease, in a common dress.

But, long before the empire of Heraclius, there had been a feast of the same denomination observed both in the Greek and Latin churches, on occasion of what our Saviour said in St. John, xii. 32. "And I, if I be exalted, or lifted up, will draw all men unto me." And again, in ch. viii. ver. 28. "When ye have exalted, or lifted up, the Son of man, then shall ye know that I am he." F. Du Soulier assures us, that M. Chastelain was of opinion, this feast had been instituted, at least at Jerusalem, two hundred and forty years before Heraclius.

The feast of the dedication of the temple built by Constantine, was held, says Nicephorus, on the fourteenth of September, the day on which the temple had been consecrated,

in the year 335; and this feast was also called the exaltation of the cross, because it was a ceremony therein, for the bishop of Jerusalem to ascend a high place, built by Constantine for that purpose, in manner of a pulpit, called by the Greeks, the "sacred mysteries of God," or, "the holiness of God," and there hoist up the cross, for all the people to see it.

**EXALTATION**, in *Physics*, denotes the act, or operation, of elevating, purifying, subtilizing, or perfecting, any natural body, its principles and parts; also the quality, or disposition, which bodies acquire by such operation.

The term exaltation has been peculiarly affected by the ancient chemists and alchemists; who imagining it to have some extraordinary emphasis, are employing it on every occasion.

**EXALTATION**, in *Astrology*, is a dignity which a planet acquires in certain signs, or parts of the zodiac; which dignity is supposed to give it an extraordinary virtue, efficacy, and influence. The opposite sign, or part of the zodiac, is called the dejection of the planet.

Thus, the 15th degree of Cancer is the exaltation of Jupiter, according to Albumazar, because it was the ascendant of that planet at the time of the creation; that of the sun is in the 19th degree of Aries; and its dejection in Libra; that of the moon is in Taurus, &c. Ptolemy gives the reason of this in his first book *De Quadrup.*

**EXAMEN**, or **EXAMINATION**, an exact and careful search, or inquiry, in order to discover the truth or falsehood of a thing.

**EXAMILION**, &c. See **HEXAMILION**, &c.

**EXAMINATION**, **SELF**, is a point much insisted on by divines, and particularly the ancient fathers, by way of preparation to repentance. St. Ignatius reduces it to five points; *viz.* 1. A returning of thanks to God for his benefits. 2. A begging of grace and light, to know and distinguish our sins. 3. A running over all our actions, occupations, thoughts, and words, in order to learn what has been offensive to God. 4. A begging of pardon, and conceiving a sincere sorrow for having displeased him. And, 5. Making a firm resolution not to offend him any more; and taking the necessary precautions to preserve ourselves from it.

**EXAMINATION of Bankrupt**, in *Law*. See **BANKRUPT**.

**EXAMINATION of Prisoners**. See **COMMITMENT**.

**EXAMINATION**, or **INSPECTION**, *Trial by*, is when, for the greater expedition of a cause, in some point or issue being either the principal question, or arising collaterally out of it, but being evidently the object of sense, the judges of the court, upon the testimony of their own senses, shall decide the point in dispute. Thus, in case of a suit to reverse a fine for non-age of the cognizor, or to set aside a statute or recognizance entered into by an infant; in this, and in similar cases, a writ shall issue to the sheriff (9 Rep. 31.), commanding him that he constrain the said party to appear, that it may be ascertained by the view of his body by the king's justices, whether he be of full age or not. If, however, the court, upon inspection, has any doubt of the age of the party, it may proceed to take proofs of the fact; and, particularly, may examine the infant himself upon an oath of *voir dire*, *veritatem dicere*, that is, to make true answer to such questions as the court shall demand of him; or the court may examine his mother, his godfather, or the like. (2 Roll. Abr. 573.) In like manner, if a defendant pleads in abatement of the suit that the plaintiff is dead, and one appears and calls himself the plaintiff, which the defendant denies; in this case the judges shall deter-

mine, by inspection and examination, whether he be the plaintiff or not. (9 Rep. 30.) Also, if a man be found by a jury an idiot, *à nativitate*, he may come in person into the chancery before the chancellor, or be brought there by his friends, to be inspected and examined, whether idiot or not; and if, upon such view and inquiry, it appears he is not so, the verdict of the jury, and all the proceedings thereon, are utterly void and instantly of no effect. (Ibid. 31.) The trial by inspection may be also used, upon an appeal of *maihem*, when the issue joined is whether it be *maihem* or no *maihem*, this shall be decided by the court upon inspection, for which purpose they may call in the assistance of surgeons. (2 Roll. Abr. 578.) And by analogy to this, in an action of trespass for *maihem*, the court (upon view of such *maihem* as the plaintiff has laid in his declaration, or which is certified by the judges who tried the cause to be the same as was given in evidence to the jury) may increase the damages at their own discretion (1 Sid. 108.); as may also be the case upon view of an atrocious battery. (Hardr. 408.) But then the battery must likewise be alleged so certainly in the declaration, that it may appear to be the same with the battery inspected. Also, to ascertain any circumstances relative to a particular day past, it hath been tried by an inspection of the almanac by the court. Thus, upon a writ of error from an inferior court, that of Lynn, the error assigned was that the judgment given was on a Sunday, it appearing to be on the 26th February, 26 Eliz. and upon inspection of the almanacs of that year, it was found that the 26th of February in that year actually fell upon a Sunday: this was held to be a sufficient trial, and that a trial by a jury was not necessary, although it was an error in fact, and so the judgment was reversed. (Cro. Eliz. 227.) But, in all these cases, the judges, if they conceive a doubt, may order it to be tried by a jury. Blackst. Com. vol. iii.

EXAMINATION of witnesses, in the trial by jury, derives peculiar advantage from its being conducted openly, *vivâ voce*, in the presence of all mankind. This mode of examination is much more conducive to the clearing up of truth, than the private and secret examination taken down in writing before an officer or his clerk, in the ecclesiastical courts, and all others that have borrowed their practice from the civil law, where a witness may frequently depose that in private, which he will be ashamed to testify in a public and solemn tribunal. Besides, the occasional questions of the judge, the jury, and the counsel, propounded to the witnesses on a sudden, will sift out the truth much better than a formal set of interrogatories previously penned and settled; and the confronting of adverse witnesses is also another opportunity of obtaining a clear discovery, which can never be had upon any other method of trial. Nor is the presence of the judge, during the examination, a matter of small importance; for, besides the respect and awe with which his presence will naturally inspire the witness, he is able by use and experience to keep the evidence from wandering from the point in issue. In short, by this method of examination, and this only, the persons who are to decide upon the evidence have an opportunity of observing the quality, age, education, understanding, behaviour, and inclination of the witnesses; in which points all persons must appear alike, when their depositions are reduced to writing, and read to the judge, in the absence of those who made them; and yet as much may be frequently collected from the manner in which the evidence is delivered as from the matter of it. See EVIDENCE.

EXAMINATION of witnesses in Chancery is done with a view to the proof of facts that are disputed, and their de-

positions are taken in writing, according to the manner of the civil law. For this purpose interrogatories are formed or questions in writing; which, and which only, are to be proposed to, and asked of, the witnesses in the cause. For the examination of witnesses in or near London, there is an examiner's office appointed; but for such as live in the country, a commission is granted to four commissioners, two named on each side, or any three or two of them, to take the depositions there. And if the witnesses reside beyond seas, a commission may be had to examine them there upon their own oaths, and (if foreigners) upon the oaths of skilful interpreters. And it hath been established that the deposition of an heathen who believes in the Supreme Being, taken by commission in the most solemn manner according to the custom of his own country, may be read in evidence. The commissioners are sworn to take the examinations truly and without partiality, and not to divulge them till published in the court of chancery; and their clerks are also sworn to secrecy. The witnesses are compellable by process of *sub-pœna*, as in the courts of common law, to appear and submit to examination. And when their depositions are taken, they are transmitted to the court with the same care that the answer of a defendant is sent. See COMMISSION to examine witnesses, and INTERROGATORIES.

EXAMINERS, in Chancery, are two officers, whose business is to examine, on oath, the witnesses produced on both sides, upon such interrogatories as the parties to the suit do exhibit for the purpose.

EXAMPLE, in Rhetoric, denotes an imperfect kind of induction or argumentation; whereby it is proved, that a thing which has happened on some other occasion, will happen again, on the present one, from the similitude of the cases. That is usually called an example, which is brought either to prove or illustrate some general assertion, as if one should say, that "human bodies may be brought to sustain the greatest labours by use and exercise;" and in order to prove this should relate what is said of Milo of Croton, that "by the constant practice of carrying a calf several furlongs every day, he should carry it as far after it was grown to its full size." (Erasm. Chil. p. 193.) But the word example is used in oratory for any kind of similitude; or, as Vossius defines it (Orat. Partit. l. iii. c. 7. § 16.), "When one thing is inferred from another, by reason of the likeness which appears between them." Hence it is called an "imperfect induction," which infers something from several others of a like nature. With regard to examples, we may observe, that those have the greatest force in reasoning, which are taken from facts. See INDUCTION.

EXANIA, from *ex*, out of, and *anus*, the complaint now more commonly named by practitioners in surgery prolapsus ani. See PROLAPSUS.

EXANNUAL ROLL. In the old way of exhibiting sheriff's accounts, the illeivable fines and desperate debts were transcribed into a roll, under this name, which was yearly read, to see what might be gotten by it.

EXANTHEMA, in Medicine, synonymous with *efflorescence*, from *εξ*, and *αἶμα*, a flower, a term applied by the older writers nearly in the same sense in which we now employ the word *eruption*, and comprehending every species of spot, discolouration, or elevation of the skin. The systematic nosologists at present understand by this word all eruptions on the skin, which are accompanied with fever; such as the small-pox, measles, scarlet fever, &c. Dr. Willan uses the term in a more limited sense, *viz.* to express that appearance only which is in English denominated a *rash*; which is a blush or "redness of the skin, varying as to extent, continuity, and brightness of colour, and occasioned

by an unusual quantity of blood distributed to several of the cutaneous veins, in some instances with partial extravasation." The exanthemata constitute the third order of Dr. Willan's classification of cutaneous diseases, including the measles, scarlet fever, nettle-rash, roseola, purpura, and erythema. See *CUTANEOUS diseases*, and these words respectively. See also Cullen Nosol. Method. class. i. order iii. Willan on Cutan. Dif. ord. iii.

EXARCH, *Ἐξαρχος*, in *Antiquity*, an appellation given, by the emperors of the East, to certain officers sent into Italy, in quality of vicars, or rather prefects, to defend that part of Italy which was yet under their obedience; particularly the city of Ravenna, against the Lombards, who had made themselves masters of the greatest part of the rest.

The residence of the exarch was at Ravenna; which city, with that of Rome, were all that was left to the emperors. The first exarch was Longinus, who was sent in the year 568 by the emperor Justin II. the successor of Justinian, to govern Italy in the room of Narfes. Longinus, being invested with absolute authority and power, suppressed the magistrates, who had been previously appointed to govern the provinces of Italy; and he himself took the title of exarch, which by the Greeks was given to those who presided over a diocese, and consequently over the numerous provinces of which the diocese was composed. This title was adopted by the successors of Longinus, who, residing, as he had done, at Ravenna, were on that account called the exarchs of Ravenna. They governed all Italy, naming and removing the magistrates, called dukes, at their pleasure; and to them the people had recourse in all matters of consequence. Longinus was sent by Justin to rule all Italy; but a great part of that country, in the first year of his government, was seized on by the Lombards, who had been called in by Narfes. This magistrate maintained the power and authority of the emperors of the East in Italy for the space of 183 years, that is, from the year 568, when Longinus was sent into Italy, to the year 751, when Eutychius, the last exarch, was expelled, and Ravenna taken by Astulphus, or Astolphus, king of the Lombards. See **LOMBARDS**.

According to Gibbon (*Decline and Fall of the Roman Empire*, vol. vii.) Narfes was the first and most powerful of the exarchs, and administered above fifteen years the kingdom of Italy. A duke was stationed for the defence and military command of each of the principal cities of Italy; and the eye of Narfes pervaded the ample prospect from Calabria to the Alps. During a period of 200 years, says the historian, (vol. viii.) Italy was unequally divided between the kingdom of the Lombards and the exarchate of Ravenna; and 12 successive exarchs were invested, in the decline of the empire, with the full remains of civil, of military, and even of ecclesiastical power. Their immediate jurisdiction, which was afterwards consecrated as the patrimony of St. Peter, extended over the modern Romagna, the marshes or valleys of Ferrara and Commachio, five maritime cities from Rimini to Ancona, and a second, inland Pentapolis, between the Adriatic coast and the hills of the Apennines. Three subordinate provinces, of Rome, of Venice, and of Naples, which were separated by hostile lands from the palace of Ravenna, acknowledged, both in peace and war, the supremacy of the exarch. The remainder of Italy was possessed by the Lombards. When Astulphus, as we have already mentioned, had made himself master of the exarchate, he thought that he had a just title to all the places depending on that domain, and consequently to the Roman dukedom and to Rome itself. He, therefore, required by a mes-

ger the inhabitants of that city to acknowledge him for their sovereign; and at the same time began his march towards Rome. The pope, Stephen II., was alarmed, and attempted to divert Astulphus from his declared purpose of plundering Rome and massacring the inhabitants, by a solemn embassy; but the king, rejecting the presents accompanying this embassy, insisted upon being acknowledged by the pope and the Romans for their sovereign. The pope in this distress applies to the emperor; but Constantine was not in a condition to assist him. He then determined to recur to the protection of France, which had been transferred, some years before, from the Merovingian to the Carolingian line; and the celebrated Pepin, son to Charles Martel, was then king. Indeed Pepin had previously promised to pope Zachary, that he would protect his see against all its enemies, especially against the Lombards. Pope Stephen visited France in person; and having stated the deplorable condition to which he was reduced by the Lombards, and implored his assistance and protection, Pepin promised to assist him against the Lombards with the whole strength of his kingdom, and to drive them out of the exarchate and Pentapolis, which were to be restored, as Pepin understood, to the emperor, from whom the Lombards had taken them; but the pope, finding the king well-disposed, took advantage of this favourable opportunity for aggrandizing himself; and, therefore, insinuated to Pepin, that he could not better acquit himself of his obligations to the apostolic see, consult the welfare of his soul, or reward him for the dangers he had undergone, and the pains he had taken for the safety of Italy, and the church, than by granting both the exarchate and Pentapolis to St. Peter, that is, to himself. The pope, at the same time, pretended that Constantine had forfeited all right to those countries, by forsaking the protection of Italy, and persecuting the church. Pepin not only put him in possession of the exarchate and Pentapolis, if he should succeed in expelling the Lombards, but confirmed his promise with an oath, in which his sons Charles and Carloman concurred. In consequence of this engagement Pepin marched with his army against the Lombards, and having routed them, Astulphus fled precipitately to Pavia. Pepin pursued him, and having besieged his capital, granted him peace on condition of his restoring the places which he had seized in the Roman dukedom, together with the exarchate and Pentapolis, to the pope. Hostages were also delivered in order to secure the fulfilment of this condition. Astulphus, regardless of his oath and hostages, invaded the Roman dukedom, seized several cities, and besieged Rome itself. In this extremity, Stephen had again recourse to his protector, who, highly incensed at the treachery of Astulphus, marched again into Italy, and closely invested Pavia, into which the Lombard king had retired. Astulphus once more sued for peace, which was granted him upon his promising to perform immediately the treaty made the year before, and, besides, to surrender to the pope the city of Commachio, which was then a place of great importance. Pepin then renewed his donation; and having caused a new instrument to be drawn up, he caused it to be delivered, signed by himself, by his two sons, Charles and Carloman, and by the chief barons and prelates of France, into the pope's hands. He then left Italy, and returned with his army to France. The exarchate comprised, according to Sigonius (ad ann. 756) the following cities, *viz.* Ravenna, Bologna, Imola, Faenza, Forlimpopoli, Forli, Cesena, Bobbio, Ferrara, Commachio, Adria, Servia, and Secchia, which were all delivered to the pope, except Faenza and Ferrara. Pentapolis, or Morea d'Ancona, comprehended Rimini,

Pesaro, Conca, Fano, Sinigaglia, Ancona, Osimo, Umarna, Jesi, Fossombrone, Monteferetro, Urbino, the Baloesian territory, Cagli, Luceoli, and Eugubio, with their territories and districts. as appears by the donation of Lewis the Pious, by which Pepin's donation was confirmed. The pope committed the government of the exarchate to the archbishop of Ravenna, who thereupon took the title of exarch, not as archbishop, but as an officer of the pope, now a temporal prince. Thus was the sceptre added to the keys, the sovereignty to the priesthood, and the popes were enriched with the spoils of the Lombard kings, and the Roman emperors. As those countries belonged, without doubt, to Constantine their emperor, some authors have thought that this donation was made in his name, and that this gave rise to the fable of the donation of Constantine the Great. Hence it appears that the popes by degrees became sovereigns of Rome. The exarchate of Ravenna, says Petrus de Marca, being yielded to the pope, the government of Rome, of course, devolved upon him; for the Roman dukedom had been always subject to the exarch. The pope, therefore, when he became master of the exarchate, claimed the administration, and continued to govern Rome, not as sovereign, but only with the authority that had been vested in the exarch, till the year 876, when the authority of the emperors, successors of Charlemagne, declining in Italy, Charles the Bald yielded all his claim to, and sovereignty over Rome, to the apostolic see. Hence Constantine Porphyrogenitus, describing the state of Europe in his time, that is, about the year 914, writes, that Rome was subject to the pope, as its sovereign. It was upon the declension of the western empire, when it was confined to Germany alone, that the pope, as well as the several princes of Italy, assumed the sovereignty, which they afterwards enjoyed. The donation of Pepin was confirmed by Charlemagne at the request of pope Adrian; for having ordered Iterius, his secretary, to draw up a new instrument, he signed it himself, caused it to be signed by the abbots, bishops, and other great men, who had attended him to Rome, and, with his own hand, laid it on the altar of St. Peter.

F. Papebroch, in his Propylæum ad Acta Sancti Maii, has a dissertation on the power and office of the exarch of Italy, in the election and ordination of the pope.

The emperor Frederic created Heraclius, archbishop of Lyons, a descendant of the illustrious house of Montboissier, exarch of the whole kingdom of Burgundy; a dignity, till that time, unknown any where but in Italy, particularly in the city of Ravenna. Menestrier. Hist. de Lyons.

Homer, Philo, and other ancient authors, give likewise the name exarchus to the choragus, or master of the singers, in the ancient choruses, or him who sung first; the word αρχων, or αρχουσι, signifying equally to begin, and to command.

EXARCH of a diocese, was anciently the same with primate. This dignity was inferior to the patriarchal, yet greater than the metropolitan.

EXARCH also denotes an officer still subsisting in the Greek church; being a kind of deputy or legate *a latere* of the patriarch, whose office it is to visit the provinces allotted him, in order to inform himself of the lives and manners of the clergy; take cognizance of ecclesiastical causes; the manner of celebrating divine service; the administration of the sacraments, particularly confession; the observance of the canons; monastic discipline; affairs of marriages, divorces, &c. but, above all, to take an account of the several revenues which the patriarch receives from several

churches; and particularly as to what regards the collecting of the same.

The exarch, after having greatly enriched himself in his post, frequently rises to the patriarchate itself.

EXARCH is also used, in the *Eastern Church Antiquity*, for a general, or superior over several monasteries; the same that we otherwise call archimandrite: being exempted, by the patriarch of Constantinople, from the jurisdiction of the bishops; as are now the generals of the Romish monastic orders.

In 493, Sebas was established exarch, or chief, of all the anchorets within the territory of Jerusalem. Du Bois.

EXA'RMA, from εξαρμαι, to be elevated, in Surgery, a high, prominent, swelling.

EXARTHREMA, from εξ, out of, and αρθρον, a joint, an old term, having the same signification as the word dislocation. See LUXATION.

EXA'RTHROS, from εξ, out of, and αρθρον, a joint, a term denoting a person whose joints are so large and mis-shapen, that they look as if they were luxated.

EXARTICULATION, a dislocation of some of the jointed bones; or a breach of articulation. See LUXATION.

EXAUCTORATIO, among the Romans, differed from *missio*, or a discharge. In the latter, the soldiers were quite dismissed from the service; and this was done after they had served twenty years: but in the former case, they only lost their pay, being still kept under their colours or *vexilla*, though not under the eagle, *aquila*, which was the standard of the legion. Whence, instead of *legionarii*, they were called *subsignani*, and were still retained till they had either served out their time, or had lands assigned them. The *exauctoratio* commonly took place after they had served seventeen years.

EXAUDET, in *Biography*, a performer on the violin in the opera band at Paris from 1749 to 1760; remarkable for nothing as a composer, but for the minuet which bears his name in France, and which in England is better known by the title of "Marshall Saxe's Minuet," the best "Minuetto per ballo," or for dancing, perhaps, that ever was composed.

EXCALCEATION, *ex, off, and calceus, shoe, discalceation*, or the act of putting off the shoes.

Among the Hebrews there was a particular law, whereby a widow, whom her husband's brother refused to marry, had a right to summon him into a court of justice; and, upon his refusal, might excalceate him, *i. e.* pull off one of his shoes, and spit in his face; which were both actions of great ignominy among that people.

The house of the person who had undergone them was thenceforward called the house of the excalceated.

EXALCED, EXCALCEATI, different orders of friars, hermits, and nuns, who amongst their other austerities went barefooted, or wore nothing on their feet but sandals, were distinguished by the name of excalced, as the Franciscans, Carmelites, Poor Clares, &c. whilst other branches of the same institute, but less rigid, were called calced, from their members wearing shoes. A particular branch of the Waldenses, Vaudois, or poor men of Lyons, in the 12th century, laid great stress on the wearing of sabots or wooden clogs instead of shoes, and therefore obtained the name of Sabatati and Infabatati.

EXCAMBIATOR. See EXCAMBIO, and EXCHANGE.

EXCAVATION, formed of *ex, and cavus, hollow, or cave, a pit, &c.* the act of hollowing or digging a cavity, particularly in the ground.

The excavation of the foundations of a building, by the Italians

Italians called *cavatione*, is settled by Palladio at a sixth part of the height of the whole building: unless there be cellars underground, in which case he would have it somewhat more.

EXCAVATION of *Vallies*, in *Geology*, is a subject which has exercised the thoughts of many ingenious men, the greater part of whom have supposed that these stupendous and important operations were effected by violent currents of water, which at some period made their way down them: but a more careful examination has shewn, that in scarcely any instances are the excavated materials to be found, or any part of them, as must inevitably have happened at the bends and junctions of vallies, particularly those which lie far inland, had the mere washing of water been the cause of vallies: but Mr. Farey, and Dr. William Richardson, have of late, and separately as it should seem, come to the conclusion (*Philosophical Magazine*, vol. xxxiii. p. 204 and 262.) that these excavations were effected by causes acting "from above the surface of the earth," which completely carried off the matter which once filled up the vallies, and originally joined those corresponding parts of strata, whose edges are now in a great number of instances to be traced in their opposite sides: these opinions of the former gentlemen have been already slightly noticed, and referred to, in our articles COAL, COLLIERY, and others.

EXCELLENCY, a quality, or title of honour given to ambassadors, and other persons, who are not qualified for that of highness, as not being princes; and yet are to be elevated above the other inferior dignities.

In England, and France, the title is now peculiar to ambassadors: but it is very common in Germany and Italy. Those to whom it was first appropriated were the princes of the blood of the several royal houses; but they quitted it for that of highness, upon several great lords assuming excellency.

The ambassadors have only borne it since the year 1593, when Henry IV. of France sent the duke de Nevers ambassador to the pope, when he was first complimented with excellency. After that, the same appellation was given to all the other ambassadors residing at that court; from whence the practice spread through the other courts.

The ambassadors of Venice have only had it since the year 1636, when the emperor and king of Spain consented to allow it them.

The ambassadors of the crowned heads dispute the giving of that title to the ambassadors from the princes of Italy; where the practice is not established.

The court of Rome never allowed the quality of excellency to any ambassador who was a churchman, as judging it a secular title. The common rules and measures of excellency were a little variable, with respect to the court of Rome. The ambassadors of France, at Rome, anciently gave the title of excellency to all the relations of the pope then reigning; to the Constable Colonna; to the duke of Bracciano, and the eldest sons of all those lords; as also the dukes of Savelli, Cesarini, &c. But they have been since more reserved in this respect; though they still honoured all the Roman princeesses with excellency.

The court of Rome, in their turn, and the Roman princes, bestowed the same title on the chancellor, ministers, and secretaries of state, and presidents of the sovereign courts of France; the presidents of the councils in Spain; the chancellor of Poland; and those of the first dignities of other states, if they were not ecclesiastics.

The word excellency was, anciently, a title of kings and emperors; accordingly Anastasius the library-keeper calls Charlemagne his excellency. The same title is still given

to the senate of Venice: where, after saluting the doge under the title of *serenissimo*, the senators are addressed under those of your excellencies. The *Liber Diurnis Pontif. Rom.* gives the title excellency to the exarch and patricians.

The Italian and French have improved on simple excellency; and made *excellentissimo*, and *excellentissime*, which have been bestowed on certain popes, kings, &c.

EXCELSIS. See GLORIA in *excelsis*.

EXCENTRIC, in *Geometry*, is applied where two circles, or spheres, though contained, in some measure, within each other, yet have not the same centre; and, consequently, are not parallel; in opposition to concentric, where they are parallel, having one and the same common centre. The sun's orbit is excentric, with regard to the globe of our earth: Mars is very excentric, with regard to the sun; that is, his motion is about a very different centre.

EXCENTRIC *Theory*, in *Ancient Astronomy*, one of the theories adopted by the ancient astronomers to explain and calculate the different irregularities which they had observed to take place in the motions of the heavenly bodies.

It is not exactly ascertained at what period practical astronomy had attained sufficient perfection to indicate the necessity of such a theory. Probably both the Indian and Egyptian astronomers were early acquainted with the more obvious inequality in the sun's orbit; but Hipparchus is the first astronomical writer who seems to have aimed at determining it with any degree of precision.

The theory embraced by Hipparchus is said to have been first taught in Greece by the disciples of Pythagoras. Though their knowledge on the subject is supposed to have been derived from the oriental nations, yet it is highly probable they contributed to strengthen the prejudices in favour of circular and uniform motion, which afterwards proved the source of so much difficulty and error in all the systems of ancient astronomy. It was from this prejudice, early assumed as a principle, that nature could not, consistently with the observed simplicity of her designs, adopt any other form for the celestial orbits than that of perfect circles, nor any other motion than what was perfectly uniform. The problem, therefore, that occupied the astronomers and philosophers of those days, was to explain the various irregularities which they observed in the planetary motions, without infringing on the above principle.

There were two theories chosen for this purpose, nearly equivalent in their principle, the concentric and the excentric.

In the concentric theory the earth was supposed to be placed in the centre of a circle, on the circumference of which the centre of another circle revolved, and on the circumference of this second circle, called an epicycle, the planet was supposed to move. The first circle was called the *deferent*, and by assigning a suitable ratio to the deferent circle, and to its corresponding epicycle, some of the more obvious irregularities were pretty accurately represented. *Fig. 110. Plate XIII. Astronomy*, is the representation of the concentric theory. Let C be the centre both of the earth and of the circle F B D, and let H G K be a smaller circle, or epicycle, whose centre B moves uniformly in the circumference F B D, from west to east, or *in consequentia*, while the sun moves also uniformly and with the same velocity in the circumference of the epicycle, *in antecedentia* in the upper part, but *in consequentia* in the lower part. If the point G of the epicycle, called its apogee, as being most distant from the earth, be supposed at the beginning of the anomalistic revolution to be placed in the point A of C F produced; and if when it comes to G, the arc G H be taken similar to F B, the point H will

be the place of the sun when the centre of the epicycle has moved from F to B. If then in CF, to which BH is parallel, we take CE = BH, and on E as a centre, with the distance EA = CF, describe the circle AHP, the sun would be seen from E to move in this circle equably; for the angle AEH is equal to the angle FCB; but seen from C, the centre of the earth, it will appear to move in it inequably; for the angle ACH, in the first circle of anomaly, that is, in the passage of the sun from A to P, is always less than AEH or FCB; and its true place H will be less advanced in longitude than its mean place B. When again the centre of the epicycle or the mean place of the sun, having described a semicircle, shall have come to D, the sun, having described a semicircle of the epicycle, will be found in P, the perigee of the orbit AHP, and its mean and true places B and H will be seen from C to coincide as they did in the apogee A. But in the sun's passage from P to A, that is, in the second semicircle of anomaly, his true place H, as seen from C, will be always more advanced in longitude than his mean place B: for in this semicircle the angle PCH is always greater than PEH or DCB. The angle EHC or BCH, which is the difference between the mean and true places of the sun, is called the equation of the orbit, and it is evident that this equation will be greatest in N or M, where the centre B of the epicycle is 90° distant from either of the apses.

It was thus that the ancients originally proceeded in their representation of the solar inequalities, and the representation seemed to be sufficiently justified by observation: at least, till the days of T. Brahé, no observations had been made with sufficient accuracy to subject it to suspicion. Their success also, while no lunar inequality except the simple anomalistical one was discovered, was equal in the application of the same concentric theory to the motions of the moon: and having, in two cases, thus successfully, by means of one subordinate sphere or epicycle, reconciled apparent inequality of motion with real uniformity, it was natural to suppose that other inequalities, though more various and complicated, might be explained in a similar manner, and required only the addition of other epicycles. The same method of procedure, therefore, was continued, and every new inequality which observation discovered, was accounted for by a new sphere or epicycle producing it, till the whole number employed in the system amounted to 34. Aristotle, on narrower examination, found these insufficient, and added to them 22: but still they were deemed insufficient; and the number was at last increased to 72. But though it was not till long after the days of Aristotle, that the theory was carried to such a degree of extravagance, the multiplication of epicycles rendered it, even in his time, almost as intricate and complex as the appearances which it was intended to explain. Some examples of this kind will occur on the revival of it by Copernicus and T. Brahé: and when Hipparchus and Ptolemy introduced excentric orbits, and by means of them somewhat diminished the multiplicity of the spheres employed by their predecessors, they were thought to do a signal service to astronomy.

The manner in which Hipparchus explained the solar inequalities, in his excentric theory, was to this purpose. Let O (fig. III.) be the centre of the earth and of the starry sphere. Let BCDE be the ecliptic, or great circle in the *primum mobile* in which the sun seems to perform his annual revolutions; and, in the same plane, but on a different centre Z, let the circle ALP be described. This is the circle, or orbit, in which the sun is supposed actually to move, and to describe round its centre equal arcs or angles in equal

times: or rather, he is supposed to be carried round by the equable motion of the circle itself; which, because its centre is not occupied by the earth, is called an excentric circle. It is evident, in this representation, that if the earth were placed in Z, a spectator on it would perceive the sun, since he is supposed to move uniformly in the excentric, to move also uniformly in the ecliptic. But the earth is placed in O, at the distance OZ from the centre of the excentric; and therefore, when his motions are referred to the ecliptic by a spectator in O, they must appear unequal. When, for example, he departs from A the apogee of the excentric, and comes to K, he would be seen from Z in the point R of the ecliptic; but from O, the centre of the earth, he is seen in C, a point less advanced in longitude. On the contrary, when he departs from P, the perigee of the excentric, and comes to N, his place in the ecliptic, as seen from Z, is the point V; but seen from O it is the point F, more advanced in longitude than V. Any line, as ZK, drawn from the centre of the excentric to the sun, or any parallel to it drawn from O, is called the line of mean motion, and determines the mean anomaly AZK; and any line, as OK, drawn from the sun to the centre of the earth, is called the line of true motion, and determines the true anomaly AOK; and the angle OKZ, which is the difference between the mean and true anomalies, is the equation of the orbit. In the apogee and perigee this equation vanishes, in the same manner as in the concentric theory; because there the lines of mean and true motion coincide; and at the points L, L, where a perpendicular to the line of apses, drawn through O, meets the excentric, it comes to its greatest amount. Thus, by the single supposition that the solar orbit was excentric to the earth, Hipparchus supplied the place of the epicycle added to the concentric: nor is it difficult to perceive that the representations, given by both theories of the solar inequalities, were in their effects precisely the same.

In both these theories, it is evident that the inequalities of the sun were considered as purely optical: and what was principally required was to find the point O, in the line AP of the apses, in which the earth must be situated, in order to give to the solar motions the just inequality which observation required; and to determine the longitude A of the solar apogee, that is, the point B of the ecliptic to which it is referred from O. Without finding the just excentricity OZ, the calculated differences, or equations, between the sun's mean and true places, would not correspond with the observed differences: and without discovering the position of the apogee, the calculated equations, however accurate, would not be applied in their proper places. In these investigations the procedure of Hipparchus was as follows.

Let B (fig. 112.) be the place of the sun at the vernal equinox, BD an arc of the excentric equal to his mean motion for 94½ days, that is, from the vernal equinox to the summer solstice, DF an arc equal to his mean motion for 92½ days, or from that solstice to the autumnal equinox: let the chord BF be drawn, and from D another chord DE perpendicular to BF. The point E of the intersection of these chords is evidently the point where the earth must be situated: for it is the only point from which B, D, F, G, can appear at the distance of 90° from one another, and as they appear actually in the heavens.

It was required, therefore, to determine the excentricity EC, or the distance of the point E from C, the centre of the solar orbit. Since the arc BDF of the mean motion, and which the ancients supposed to be the only real motion of the sun, from B the vernal to F the autumnal

nal equinox, is given by means of the annual revolution, and consists of  $184^{\circ} 20'$ , its half BH will consist of  $92^{\circ} 10'$ . Through H draw the diameter HC; and through C the centre of the orbit, the diameter CK perpendicular to HC, and meeting DE in L; and join CE. If from BD, the mean motion for  $94\frac{1}{2}$  days, and  $=93^{\circ} 9'$  we subtract BH  $=92^{\circ} 10'$ , the remainder DH will be found  $=59'$ : and if from BH we subtract the quadrant KH, the remainder BK will be  $=2^{\circ} 10'$ . Therefore CL and EL, the sines of the arcs DH, BK, will be given in parts of CD  $=10,000$ ; the former to wit  $=172$ , and the latter  $=378$ . Therefore the excentricity EC, being the hypotheuse of the right-angled triangle ELC, will be found in the same parts: for  $EC^2 = CL^2 + EL^2$ , and therefore  $EC = 415$ .

By producing EC to meet the excentric in A and P, we shall have the line AP of the apsidcs: and the longitude of A the apogee will be found from the same triangle ELC; for  $CE : EL :: R : \sin. ECL = KCA = BEA = 65^{\circ} 30'$ . Since B therefore represents the point of Aries, the place A of the apogee fell short of the solstitial point D,  $24^{\circ} 30'$ , in the days of Hipparchus. It is now between  $9^{\circ}$  and  $10^{\circ}$  more advanced.

When the excentricity and the longitude of the apsidcs were thus determined, the equations of the orbit, or the differences between the mean and true places of the sun, were obtained by a very simple trigonometrical computation. For in the excentric theory, (fig. 111.) when this equation comes to its greatest magnitude, in the points L, L, or M, M, where perpendiculars to the line of apsidcs drawn through O or Z meet the excentric, the excentricity OZ becomes the tangent of the angle ZMO to the radius of the orbit ZM: and at any other point K, with the excentricity OZ, the radius ZK, and the angle KZO the supplement of the mean anomaly AZK, the equation ZKO will be found by the analogy  $KZ + ZO : KZ - ZO :: \tan. \frac{1}{2} AZK : \tan. \frac{1}{2} (ZOK - ZKO)$ . The calculation will be precisely the same in the concentric theory if EC be taken in CA, (fig. 110.) equal to the radius of the epicycle, that is, to the excentricity OZ, (fig. 111.) and will produce the same results: and the excentric theory will be found to differ from the concentric only in simplicity. It is probably needless to observe that the parallels OL and ZM will mark the same point in the zodiac.

Though these theories were thought sufficient to explain the solar motion, in that imperfect state of practical astronomy, yet they were found entirely to fail when applied to the observed motions of the moon and planets. A new scheme was therefore adopted by Ptolemy, in which, however, the principle of uniform motion was in fact abandoned. This consisted in assuming an imaginary point as the centre of a new circle, called the equant; and it was supposed that to a spectator situated in that point the motion of the planet would appear to be uniform. It is not now exactly known if the Greek astronomers invented this theory, or if they received it by tradition from the eastern nations, but it is a curious circumstance to observe, in the history of the science of astronomy, how very near the truth the ancients arrived by trial and observation; for their deferent circle and epicycle reduced the figure of the orbit really to an oval form, and the two points in which they placed the earth and the centre of the equant were many centuries afterwards discovered to be no other than the foci of an elliptic orbit. The true theory was kept out of sight by an obstinate adherence to an ancient prejudice, for what a singular method was nature supposed to take, in order to adhere to this principle of uniform and

circular motion; after a number of unmeaning efforts, she only accomplished an *apparent* uniform motion round an imaginary point, in which no spectator could ever possibly be placed to admire the beauty of the contrivance:

The mode of determining the equant was as follows.

Let A be the centre of the earth, (fig. 113.) suppose the centre of the world D, the centre of the orbit of a planet, or of the excentric circle, F K M L E, called the deferent, (see EPICYCLE.) Upon the point F is described the epicycle G Q, and above D a point E is assumed, equal to the excentricity AD, and from the point E another circle is described, R K O L R, of the same magnitude as the deferent. This second circle is called the equant, because the centre of the epicycle, which moves upon the deferent, has nevertheless an equal motion round the centre E of the equant, for the epicycle describes its deferent with an unequal motion, which should disappear when referred to the centre of the equant, so that the angle, such as FEI, formed by the line of apsidcs AF, and by the line drawn to the centre of the epicycle, arrived at I, may be always equal in equal times; for this reason Ptolemy calls the point E the point of equality. The angle FAI is the true anomaly of the excentric, the angle FEI the mean anomaly, and which is always formed at the centre of the equant.

Kepler had endeavoured to explain physically the cause of the equant, that is, why there should be a point E different from the point D, about which the motion was regular and uniform, (Mystr. Cosmog. c. 22.) He was persuaded the cause was general, and that the equant must take place in the orbit of the earth, as well as in the other planets. Neither Tycho nor Copernicus had employed an equant, but Kepler was persuaded that the points E and D in an excentric were not the same, particularly when Tycho informed him that the annual orbit, or excentric of the sun, appeared to him not to be always the same.

Kepler suspected that this variation arose from the point of equality not being the centre of the circle; and in the course of his investigation of this question, he was led to the discovery of the bisection of the excentricity in the case of the earth, whereas the ancients only admitted it in the case of the superior planets. See EXCENTRICITY, *bisection of*.

EXCENTRICITY of the Orbit of a Planet, in Astronomy, is the distance between the centre and the focus of the ellipse in which it revolves. The discovery of the excentricity in the orbits of the sun and moon is attributed to Hipparchus, who wrote a treatise on this subject 150 years before our era.

The excentricity of the orbit is computed from the greatest equation of the centre, by the following proportion: As  $57^{\circ} 17' 44''.8$ , (the arc = rad.) is to half the greatest equation, so is rad. = 1 to the excentricity. See EQUATION, and ELLIPTIC Motion.

But when the greatest equation has been found, and accurately determined by observation, the excentricity may be practically deduced by using the rule of false position, or by supposing the excentricity known, and finding by trial the greatest equation corresponding to it.

The excentricities of the planetary orbits are usually calculated on a scale which supposes the mean distance of the earth from the sun divided into one hundred thousand parts, and the excentricity is expressed in proportional parts of that scale.

The following formula for calculating the excentricity is given by Lambert in the Ephem. de Berlin.

Let

Let  $E$  be the greatest equation of the centre,  $e$  the excentricity, make  $\frac{E}{57} = \alpha$ .

The excentricity will then be expressed by the following series.

$$e = \frac{1}{2} \alpha - \frac{11}{768} \alpha^3 - \frac{587}{93040} \alpha^5 - \frac{40583}{2642411520} \alpha^7 - \dots$$

The quantity  $\alpha$  is always a small fraction, particularly for the sun; if we suppose with La Place,  $E = 2^{\circ}.1409$  decimal for 1750. Then,

$$\alpha = \frac{2.1409}{63.6620} = 0.033629$$

$$\frac{1}{2} \alpha = 0.016814.$$

The second term,  $\frac{11}{768} \alpha^3$ , is less than 0.000001, and may therefore be entirely neglected.

TABLE of Excentricities according to different Authors.

Planets.	Kepler.	Cassini.	Halley.	La Lande.	Log. of Excen. in parts of the mean distance.
Mercury	8150	8092.1	7970	7955.4	9.3128399
Venus	501	517	504.985	498	7.8378910
The Sun	1800	169	1691.90	1681.395	8.2253628
Mars	14115.5	14155	14170	14183.7	8.9688921
Jupiter	25074	2506	25078.6	25013.3	8.6819346
Saturn	54143.5	5432	54381.4	53640.42	8.7499109
Herfchel				90804	8.6774873

The following table of excentricities in parts of the major axis is taken from the "System of the World," by La Place.

Mercury	-	0.205513
Venus	-	0.006885
Earth	-	0.016814
Mars	-	0.093808
Jupiter	-	0.048877
Saturn	-	0.056223
Uranus	-	0.046683

The secular variation of these numbers is as follows: (the sign - indicates a diminution.)

Mercury	-	+ 0.000003369
Venus	-	- 0.000062905
The Earth	-	- 0.000045572
Mars	-	+ 0.000090685
Jupiter	-	+ 0.000134254
Saturn	-	- 0.000261553
Uranus	-	- 0.00026228

**EXCENTRICITY, bisection of.** The bisection of the excentricity is a curious principle assumed by Ptolemy, and the ancient astronomers, to explain the irregularities of the planetary motions. It is thus described by Dr. Small.

The inequalities of the planets were so various and intricate, that the explications of them were for a long time extremely imperfect, and so partial, that no Grecian astronomer before Ptolemy had supposed it practicable to give a compleat theory of all. In the more ancient times the explications of them appear to have been made by orbits concentric to the earth, and charged with epicycles: but, as Ptolemy had found no method of representing the second inequalities, except by means of epicycles, so, to avoid the perplexity occasioned by the multiplication of them, he gave the preference to an excentric orbit for the

representation of the first; and, by the superior simplicity of the representation, the authority of the excentric theory was for many centuries established. With respect to those first inequalities, at least of the superior planets, it appears to have been originally supposed, that they might be sufficiently accounted for by the more simple solar hypothesis. For, if the planet, in consequence of its second inequalities, be represented as moving in the circumference  $abc$  (fig. 111) of an epicycle, the centre  $ALPQ$ , of this epicycle, will represent the places which it would occupy, if it were divested of all second inequality: and it was thought a sufficient explication of the first inequality, to suppose that this centre moved equally round  $Z$ , the centre of the orbit, and consequently inequally round  $O$ , the centre of the earth. But when, according to Kepler's conjectures on this subject, they endeavoured to account for the inequality of the latitudes in opposition, and of the digressions of the planets, especially their greatest digressions, from the point opposite to the sun, by variations of their distances from  $O$ , it appeared that the point  $Z$ , round which the planet moved equably, could not be the same with the centre of the orbit; for, both the latitudes, and also the angles  $aOe$ ,  $dOf$ , which the epicycle subtended at the centre of the earth, were found to be greater at the apogee, and less at the perigee than the limits of the excentric  $ALPQ$  permitted; and that, consequently, the centre of the orbit occupied a place nearer than  $Z$  to the centre of the earth. It was therefore a matter of much greater difficulty to form an hypothesis for the motions of the planets, than for those of the sun: for, if their first inequalities required one determined excentricity, or distance between the centre of uniform motion and the centre of the earth, the variations of their latitudes, and of their second inequalities, shewed that this was not the excentricity of the orbit in which the epicycle moved, and that this orbit evidently required another. In what proportion the distance  $ZO$  between the centre of uniform motion and the centre of the earth ought to be divided by the centre of the orbit, appears to have been for a long time a matter of much uncertainty. But Ptolemy tells us that, on applying himself to investigate the measure of the approach of the centre of the epicycle, within the circle  $ALPO$  at the apogee, and its consequent withdrawing from it beyond the perigee, he found, by multiplied observations, that the centre of the orbit lay precisely in the middle, between  $Z$  the centre of uniform motion, and  $O$  the centre of the earth. This is the famous principle, known by the name of the bisection of the excentricity: and, as Ptolemy gives no account of the means by which it was discovered, nor of the observations from which it was inferred, his assuming it has justly excited the wonder of all astronomers. The greater part believed him to have assumed it merely from conjecture, and not to have derived it, as Kepler more generously supposed, from any observations; and there seems to be some reason for thinking that it came to him by tradition, from the more ancient astronomy of the East.

**EXCEPTIO**, in the Roman Law. See PLEADING.

**EXCEPTION**, something reserved, or set aside, and not included in a rule.

It is become proverbial, that there is no rule without an exception; intimating, that it is impossible to comprehend all the particular cases under one and the same maxim. But it is dangerous following the exception preferably to the rule.

**EXCEPTION**, in Law, is a stop or stay to an action.

The term is used indifferently, both in the civil and common

mon law; and in each exceptions are divided into *dilatory* and *peremptory*.

In law proceedings, exception is a denial of a matter alleged in bar to the action; and in chancery it is that which is alleged against the sufficiency of an answer, &c. Exception, in a general sense, includes all the kinds of defence, or vindication, which a person, against whom a process is brought, makes use of to prevent or retard its effect.

The civilians reckon three kinds of exceptions; *viz. declinatory*, whereby the authority of the judge or court is disallowed; *dilatory*, intended to defer or prevent the thing from coming to an issue; and *peremptory*, which are proper and pertinent allegations, founded on some presumption that stands for the defendant; as want of age, or other quality, in the party; or other matter that may be decided, without entering into a full discussion of the merits of the cause.

EXCEPTION *to evidence*, is where a demurrer is offered in any civil cause, on account of the insufficiency of the evidence given, and the court does not agree to it; in which case the court or judge are required to seal a bill of exceptions, by stat. Westm. 2. 13 Edw. I. cap. 31. which is in the nature of an appeal, examined in the next immediate superior court, upon a writ of error after judgment given in the court below. See DEMURRER, and EVIDENCE.

EXCEPTION, *in deeds and writings*, is the saving of a particular thing out of a general one granted by deed, as a room, shop, or cellar, out of a house; a field, or timber-trees, out of land, &c. Exceptions of this kind must not cross the grant, nor be repugnant to it, or else they are void of course; yet there may be a kind of exception, or saving out of an exception, so as to make a thing as if never excepted; as where a lease is made of a rectory, excepting the parsonage-house, saving to the lessee a chamber, this shall pass by the lease.

EXCEPTIVE CONJUNCTION. See CONJUNCTION.

EXCEPTIVE *propositions*, are those wherein something is affirmed of a whole subject, abating some one of the parts thereof, which is *excepted* by a particle, thence called an exceptive particle, or particle of exception.

Thus, "All the sects of the ancient philosophers, except the Platonists, held God to be corporeal. Covetousness is inexcusable in respect of every thing, but time."

EXCESS is distinguished into *natural* and *moral*: the first, is a part whereby one quantity is greater than another. Thus, we say, this line is longer than that; but the excess is inconsiderable.

The latter is an intemperance, or going beyond the just bounds and measures prescribed for any thing. Thus, we say, excess in wine, women, &c. is prejudicial to the health.

EXCESSIVE, in *Music*, is used as a prefix to denote the excess of certain tempered intervals above the true intervals of the same name; it is generally opposed to defective, *viz.* when there is a deficiency to the same extent as there is here an excess; but their use is not limited to any certain quantity of excess or defect, they being sometimes applied in conjunction with or to represent the diatonic, sometimes with enharmonic diatonic, at others with minimum semitone, &c.; whereas the prefixes, redundant and deficient, are used only with the major comma, and hence the word comma is sometimes omitted; and in like manner the prefixes superfluous and diminished are confined to the minor semitone, which last word is therefore sometimes omitted in naming the class of intervals, which are increased or lessened by a minor semitone.

Vol. XIII.

EXCHANGE, in *Commerce*, and *Political Economy*, is the act of paying or receiving money in one country for its equivalent in the money of another country, by means of bills of exchange.

This science, therefore, comprehends both the reduction of monies, and the negociation of bills: it determines the relative value of the currencies of all nations, and shews how foreign debts are discharged, loans and subsidies paid, and other remittances made from one place to another, without the risk or expence of transporting specie.

This important subject may be considered under the five following heads, namely:

1. Bills of exchange.—2. Par of exchange.—3. Course of exchange.—4. Monies of exchange.—5. Arbitration of exchange.

*Bills of exchange*.—A bill of exchange is a written order for the payment of a certain sum of money at an appointed time. It is a mercantile contract in which four persons are mostly concerned, *viz.* 1. The *drawer*, who receives the value. 2. His debtor in a distant place, upon whom the bill is drawn, who is called the *drawee*, and who is to accept and pay it. 3. The person who gives value for the bill, and who is called the *buyer* and *remitter*; and, 4. The person to whom it is ordered to be paid, who is called the *payee*, and who may, by indorsement, pass it to any other holder.

Most mercantile payments are made in bills of exchange, which, until due, generally pass from hand to hand, like any other circulating medium. The laws of all trading nations afford the most ready and effectual means of enforcing the payment of bills, and hence that credit which they so universally obtain, and which greatly facilitates the operations of commerce.—For the laws, customs, and regulations of bills of exchange, see BILL of exchange, and *Mercantile Law*. See also AGIO, USANCE, and DAYS of Grace.

Bills are distinguished into inland and foreign, according as they are made payable in the country where they are drawn, or in a foreign country. Their functions, however, are similar in both cases, and therefore in explaining the theory of exchange, we shall begin with the operations of inland bills as the most simple and familiar.

Suppose A. of London is creditor to B. of Edinburgh 100*l.* and C. of London debtor to D. of Edinburgh 100*l.* these two debts may be discharged by the operation of one bill: thus, A. draws on B. and sells his bill to C. who remits it to D. and the latter receives the amount from B. when due. Here, by a transfer of claims, the London debtor pays the London creditor, and the Edinburgh debtor the Edinburgh creditor.

By the foregoing example it appears that reciprocal and equal debts due between two places, may be discharged without any cash remittance, and it may be supposed that such an operation is of equal convenience to the parties concerned, in both places; but when debts are unequal, the advantage must be likewise different, as the obligation of remittance is no longer mutual; for the debtor place must pay its balance either by sending cash or bills; and as the latter mode is generally preferred for several reasons, an increased demand for such bills must be the consequence; and this enhances their price, as it would that of any other saleable article.

This is the plain principle of exchange which is constantly exemplified in the premium paid for inland bills on London; for this city, being the grand emporium of commerce that furnishes most other places of the kingdom with foreign merchandize, and being also the residence of

## EXCHANGE.

numerous landlords whose rents must be remitted to them from the country, it has generally a large balance of debt in its favour, a great part of which must be sent in bills; this creates a demand, and consequently a premium which is mostly commuted for time; thus, if A. of London be creditor to B. of Edinburgh 200*l.* and C. of London debtor to D. of Edinburgh only 100*l.* the balance of 100*l.* against Edinburgh cannot be cancelled by a transfer of claims, but must, we will suppose, be remitted by a bill, which can be only obtained at a certain number of days after date. The most general term for bills from Edinburgh on London is 40 days, and the interest for this time is about  $\frac{1}{2}$  per cent. The number of days here is called the exchange, which has been known to vary considerably according to the balance of debt, or the plenty or scarcity of bills. A similar premium or date is allowed for bills from all other places of Great Britain on the capital, but bills at sight on any of those places may be generally had in London without any premium whatever.

Although the principle of foreign exchange is the same as that of inland, yet the former is more complicated in its operations than the latter, owing to the denominations of money not being the same. This causes a difference in the mode of paying the premium for bills; in which, however, the date is taken into consideration as well as the comparative rates at which the monies are valued.

In foreign exchange one place always gives another a fixed sum or piece of money for a variable price, which fluctuates according to the balance of debt, as before stated: the former is called the certain price, and the latter the uncertain price. Thus London is said to give to Paris the certain for the uncertain; that is, the pound sterling for a variable number of francs; and to give to Spain the uncertain for the certain; that is, a variable number of pence sterling for the dollar of exchange.

Whatever the uncertain price is, at any time, is called the course of exchange. Now suppose Paris gives London 25 francs for the pound sterling, and that this sum is found to contain the same quantity of pure silver as 20 shillings, then the exchange is said to be at par; but if France should give a higher price, it is said to be in favour of London, and *vice versa*. This is the common mode of judging whether the exchange be favourable or unfavourable to a place, though it is not always the correct method, nor that which merchants generally act upon. But before we enter into any further explanation of the course of exchange, or the causes of its fluctuation, it will be necessary to explain more fully what is to be understood by the par of exchange, a subject on which there is some difference of opinion, even among writers of the first authority.

### *Par of Exchange.*

The par of exchange may be considered under two general heads; namely, the *intrinsic par*, and the *commercial par*, each of which admits of subordinate divisions and distinctions.

The intrinsic par of exchange is the value of the money of one country compared with that of another, with respect both to weight and fineness. Thus, two sums of different countries are intrinsically at par when they contain an equal quantity of the same kind of pure metal, separated from its alloy, which is always deemed of no value. See COIN.

There should be two intrinsic pars, the one between gold coins, and the other between silver coins; and hence

the intrinsic par of exchange can be only determined with accuracy between places which pay their bills in the same kind of metal, as between England and Portugal, that pay in gold coin; or between France and Spain, that pay in silver coin, for the relative value between these metals is scarcely ever the same in any two countries.

It may be even observed, that the value of the same metal differs considerably in different countries, and therefore this intrinsic par of exchange cannot be always considered as a true equality in the value of monies; thus in the case of France and Spain, where the latter country supplies the former with the materials of her silver coinage, silver must be most valuable in France, and the difference should be equivalent to the charges attending the removal, such as the duty paid (in time of peace) to the Spanish government, for the exportation of dollars, the expences of carriage, insurance, commission, interest, &c. all of which amount to nearly 7 per cent.

A similar computation might be made between gold in England and in Portugal, as the latter country supplies the former with the materials of her gold coinage.

But where one country pays its bills in gold, and another in silver, no intrinsic par of exchange whatever can be permanently established. An equivalency can be only ascertained by valuing as merchandize the gold of one place, and the silver of the other, according to the market price of the day; but this is the commercial par, which shall be more fully explained below.

In ascertaining the intrinsic par between coins of the same metal, a question occurs, whether the computation should be made according to the mint regulations of the respective countries where the monies are struck, or according to actual assays. The former is the most general method, though the latter is certainly the most correct; for while some governments make coins according to their full standard, as in England, others take advantage of the allowance for remedy, and sometimes make it a source of considerable emolument.

There are some countries with which no par of exchange, either intrinsic or commercial, can be permanently fixed. These are such as pay their bills in paper, which must have a fluctuating and precarious value. Even the bank money of Amsterdam and Hamburg comes in a certain degree within this description, as it bears a fluctuating agio against currency.

The *commercial par* is the comparative value of the monies of different countries, according to the weight, fineness, and market price of the metals. This is the par which merchants generally consider of importance in their exchange speculations, and we cannot define it better than in the following passage, taken from the Minutes of the Committee of the House of Commons, appointed in 1804, to enquire into the state of exchange between Ireland and England. Several of the most intelligent merchants of both countries were examined on the occasion, and their evidence produced much new and practical information.

In the examination of Benjamin Winthrop, esq. governor of the bank of England, an interesting enquiry and investigation took place respecting the par of exchange, from which the following appropriate question and answer are extracted.

*Question.*—"When a sum of Hamburg currency, which will buy a pound of bullion of given purity in the market of Hamburg, can purchase a bill for a sum of English currency, which will buy a pound of bullion of the same standard in the English market, is not then the exchange at par between those two countries?"

*Answer.*

## EXCHANGE.

*Answer.*—"I confess it does appear to be a complete par of exchange."

This par of exchange is variously denominated by different writers on political economy; thus it is called the *current*, the *momentary*, the *political*, and the *eventual par*; and though each of these terms seems to convey a correct idea of the subject, yet we have adopted the word *commercial* as equally appropriate and more generally understood.

Some notice might be here taken of what is called a *monetary par*, in which an allowance is made for seignorage and mint expences, and also of a *common* or *estimate par*, which generally differs from the true one; thus the pound sterling of England is estimated at 11 guilders current of Holland; but such definitions are of little utility in the illustration of exchange.

The following opinion on the par of exchange seems to deserve quotation. It is translated from the preface of a most elaborate work, entitled "Dictionnaire des Arbitrages," by Francois Corbaux, published at Paris in 1802.

"Without dwelling any longer," says this author, "on the arbitrary notions which have been formed of the par of exchange, and without seeking to adopt new ones, which might be rendered very numerous, we shall conclude by observing, that although the intrinsic or pretended real par is made the foundation and principal element in the determination of the price of exchange, yet not being the same in the gold as in the silver coins, the pars of these two metals should be kept totally distinct; and that besides, as neither of them finds any direct application in the common course of exchange affairs, it is through ignorance that so much importance has been attached to them, and that they have been considered as the most correct expression of the relative value of the monies of two countries. In short to seek for a true and rational par is to suppose what cannot exist, that is, the fixing of different principles and elements which are subject to continual variation, and, after all, if this could be accomplished, it would present no object of real utility."

However well-founded the opinion of Monsieur Corbaux may be, we think it must be at least satisfactory to merchants to understand the intrinsic par of exchange, and therefore we shall give new tables of it at the conclusion of the present article, computed both in gold and silver, with rules and examples for performing all such calculations; and shall now proceed to the explanation of the course of exchange, which is a subject of great importance, whether we consider it in a commercial or political point of view.

### *Course of Exchange.*

The course of exchange is the current price or proportion between the monies of two places; which is always fluctuating according to circumstances.

When merchants have occasion to draw or remit foreign bills, they meet upon the Royal Exchange, where this kind of business in London must be transacted. The market is constantly attended by exchange-brokers, to whom the wants of the parties who wish to buy or sell bills are privately communicated. These brokers, whose confidential situation demands strict impartiality, bring parties together; and settle the course of exchange for the day, as soon as they learn how the market stands with respect to the number of drawers and remitters. The commission for this business throughout Europe, is *one per mille* (or thousand) which is equally paid by the buyers and sellers of bills.

When the course of exchange rises above par against any country, it is then concluded that the balance of trade is against

that place. Now, if England should import from France goods to the value of 100,000*l.*, and export only to the value of 80,000*l.*, it may cost England 120,000*l.* to pay the whole debt, if it should be publicly known that so great a balance exists, and therefore secrecy is of peculiar importance in this kind of business.

The fluctuations of exchange are mostly greater or less according to the known amount of the balance, and the expence and difficulty of conveying specie. By the expence of such conveyance is meant the carriage and insurance, and by the difficulty the hazard of evading those prohibitory regulations which, in most countries, impede the exportation of coin; and so powerful is the operation of these causes, that the exchange is sometimes very high, or unequal, even between neighbouring countries, affording room for very profitable speculations for those merchants who circulate bills in the way of arbitration of exchange.

An unfavourable state of the exchange with a country furnishes a motive for exporting commodities to it. The merchant under these circumstances can afford to sell his goods as much cheaper as the premium which he receives for his bill amounts to. Hence the course of exchange tends to correct itself, and, in peace, it seldom continues, for any length of time, more unfavourable than the amount of the expences which might be incurred by transporting bullion to pay the balance which is to be remitted; for bullion may be considered the universal currency of merchants, though it is not always of ready or immediate application.

Although an unfavourable balance of trade has been generally considered an invariable cause of an unfavourable course of exchange, yet recent experience has shewn that this is not always the case. Thus, in the investigation already alluded to, which took place in the House of Commons relating to the exchange between England and Ireland, it was demonstrated that the balance of trade was in favour of Ireland, while the course of exchange was highly unfavourable; it was, however, shewn in subsequent publications on the subject by Messrs. Parnell and Forster, that though the balance of trade was in favour of Ireland, the balance of debt was unfavourable, or, in other words, the balance of remittance, on account of the number of Irish absentees resident in England; but perhaps the political state of the country was the chief cause.

In time of war the fluctuations of the course of exchange are sometimes very great, particularly where large remittances are to be made in the way of foreign loans or subsidies. The exchange is likewise lowered by any debasement of the coin of a country, or by the depreciation of any other circulating medium. Even an excess of currency has the effect of turning the rate of exchange against that place where it prevails, as the excess raises the price of all commodities beyond their value in those places where no such redundancy exists. It may, however, be observed, that the nature of exchange operates to effect the general distribution of the surplus specie, and to maintain the level of money throughout the commercial world. In short, in all cases, the exchange tends to an equilibrium.

Although the depreciation of the circulating medium of a country raises the course of exchange against it, the circumstance is not always a disadvantage. Thus, before the reformation of our silver coinage, in the reign of William the Third, the exchange between England and Holland, computed by the standard of their respective mints, was 25 *per cent.* against England, but the current coin of England was more than 25 *per cent.* below its nominal or standard value; and therefore the exchange was virtually in favour

## EXCHANGE.

of England, according to the statement of Dr. Adam Smith.

It may be further observed, that the wealth of a country will sometimes raise the course of exchange against it, on account of its importations of luxuries from abroad. Rich countries are likewise liable to have the course of exchange turned against them by the subsidies which they may have to remit to less opulent states, as before noticed.

Thus in 1793, the trade between Holland and England was completely open; and yet the course of exchange was 10 or 12 per cent. against Amsterdam, owing probably to the balance of trade being so much in favour of London. But, in 1794, when England undertook to subsidize Prussia, large remittances of bills were made through Amsterdam, which caused an immediate fall in the course of exchange between that place and London, even below par: and therefore at subsequent periods of the war, it has been thought prudent by the English government to export specie on such occasions, rather than to turn the course of exchange against London by the operation of remitting large subsidies in bills. During the present war between France and Austria (1809) the latter power has been subsidized by the English government, which has been chiefly done in bills, and this has tended to raise the exchange against England, in the places where those bills were negotiated. But the cause which has operated more powerfully to produce this effect is the great exportation of goods to England, from Germany, France, and Holland, without any adequate importation of English merchandize. Hence the exchange with London has been for some time greatly in favour of those places, while between London and most of the other parts of Europe it has continued nearly at par.

From what has been said respecting the causes, both commercial and political, which produce the fluctuations of exchange, and which frequently counteract each other, the following simple conclusion may be drawn; that whatever produces a demand for bills on any place tends to enhance their value, and therefore the course of exchange rises and falls according to the proportion which exists between the plenty and scarcity of bills, that is, between the demand and the supply.

### *Monies of Exchange.*

The following tables contain the monies of exchange of the principal trading places of Europe, in all their varieties and combinations. Explanations are also given of the quotations or lifts of the courses of exchange, which are transmitted from one country to another for the government and advice of merchants. These quotations seldom give more than the figures of the uncertain prices, omitting the denominations of money and the certain prices, all of which are here explained.

*Note.*—In all the uncertain prices the words *more or less* are to be understood.

### AMSTERDAM.

#### *Monies of Exchange.*

Exchanges are computed in florins, stivers, and pennings; or in pounds, shillings, and pence Flemish.

16 Pennings	= 1 Stiver
20 Stivers	= 1 Florin or guilder
2 Grotes or pence Flemish	= 1 Stiver
12 Grotes or 6 stivers	= 1 Shilling Flemish
20 Shillings Flemish, or 6 florins	= 1 Pound Flemish.

There are two sorts of money in Holland; namely, *banco* and *currency*: *banco* generally bears a premium against *currency* of 4 or 5 per cent. which is called *agio*.

Amsterdam gives to	<i>Quotation explained.</i>	
	Uncertain prices.	Certain prices.
London	{ 34 shillings 8 } grotes Flemish	} for 1 Pound sterling
France	54 Grotes Flemish	— 3 Francs
Spain	99 Ditto	— 1 Ducat of exch.
Portugal	44 Ditto	— 1 Old crusade
Genoa	86 Ditto	— 1 Pezza of 5¼ lire
Leghorn	92 Ditto	— 1 Pezza of 8 reals
Hamburg	34 Stivers	— 2 Marks
Vienna	20 Ditto	— 1 Rixdollar
receives from		
Antwerp	104 Florins	— 100 Florins
Breslau	144 Rixdollars	— 100 Rixdollars
Venice	96 Soldi piccoli	— 1 Florin

*N. B.* The exchanges of Amsterdam are always transacted in *banco*, unless otherwise expressed.

### AUGSBURG.

#### *Monies of Exchange.*

Exchanges are computed in florins and creutzers, and also in rixdollars and creutzers.

60 Creutzers	= 1 Florin
1½ Florin or 90 creutzers	= 1 Rixdollar of account.

Two sorts of money are used here; *giro*, that is, money of exchange, and *currency*.

100 Florins of exchange = 127 Florins current.

#### *Quotation explained.*

Augsburg gives to	<i>Quotation explained.</i>	
	Uncertain prices.	Certain prices.
Amsterdam	{ 113 Rixdollars of } exchange	} for 100 Rixdollars
Hamburg	118 Ditto Ditto	— 100 Ditto
Francfort	102 Rixdollars cur.	— 100 Ditto
Leipfic	99 Ditto Ditto	— 100 Ditto
London	{ 10 Florins 45 } creutzers	— 1 Pound sterling
Paris	120 Florins current	— 300 Francs
Nuremberg	101 Florins Ditto	— 100 Florins
receives from		
Genoa	62 Soldifuoribanco	— 1 Florin
Leghorn	{ 57 Soldi moneta } buona	— 1 Ditto
Vienna	128 Florins	— 100 Ditto.

### BERLIN.

#### *Monies of Exchange.*

Exchanges are computed in rixdollars, good groschen, and pfenings *currency*.

12 Pfenings	= 1 Good grosche
24 Good groschen	= 1 Rixdollar of account.

#### *Quotation explained.*

Berlin gives to	<i>Quotation explained.</i>	
	Uncertain prices.	Certain prices.
Amsterdam	154 Rixdollars	for 100 Rixdollars
Breslau	100½ Ditto	— 100 Ditto
Hamburg	158 Ditto	— 100 Ditto
Konigsberg	100½ Ditto	— 100 Ditto
Francfort	105 Ditto	— 100 Ditto
Leipfic	104 Ditto	— 100 Ditto
London	{ 6½ Ditto 12 } groschen	— 1 Pound sterling.
Paris	83 Rixdollars	— 300 Francs
Augsburg	106 Ditto	— 100 Rixdollars
Vienna	60 Ditto	— 100 Ditto.

### BOLOGNA.

# EXCHANGE.

**BOLOGNA.** See **ROME.**

**BREMEN.**

*Monies of Exchange.*

Exchanges are computed in rixdollars, grotos, and swares  
 5 Swares = 1 Grote  
 72 Grotos = 1 Rixdollar of account.

*Quotation explained.*

Bremen gives to	Uncertain prices.	Certain prices.

London	605 Ditto	— 100 Pounds sterling
Nuremberg	104 Ditto	— 100 Rixdollars
Paris	20 Grotos	— 1 Franc
Vienna	90 Rixdollars	— 100 Rixdollars.

**BRESLAU.** See **BERLIN.**

**CADIZ.**

*Monies of Exchange.*

Exchanges are computed in dollars, reals, and maravedis of old plate; also in ducats of exchange, and in doubloons of plate, or pistoles of exchange.

34 Maravedis = 1 Real  
 8 Reals = 1 Dollar of plate  
 375 Maravedis of plate = 1 Ducat of exchange  
 4 Dollars of plate = 1 Pistole of exchange.

*N. B.* Vellon, the current money of Spain, is to old plate as 17 to 32; that is,

32 Reals or maravedis vellon =  $\frac{1}{2}$  of 17 Reals or maravedis of old plate.

*Quotation explained.*

Cadiz gives to	Uncertain prices.	Certain prices.
Genoa	121 Dollars of plate	for 100 Pezze of 5 $\frac{3}{4}$ lire
Leghorn	130 Ditto	— 100 Pezze of 8 reals
Naples	{ 290 Maravedis of plate }	— 1 Ducat regno
receives from		
Amsterdam	97 Grotos Flemish	— 1 Ducat of exch.
London	42 Pence sterling	— 1 Dollar of plate
Paris	78 Sous tournois	— 1 Ditto
Hamburgh	90 Grotos Flemish	— 1 Ducat of exch.
Lisbon	2470 Rees	— 1 Dobloon of plate

**CONSTANTINOPLE.**

*Monies of Exchange.*

Exchanges are computed in piaftres, paras, and aspers; or in piaftres and aspers.

3 Aspers = 1 Para  
 40 Paras or 120 aspers = 1 Piaftre or dollar.

*Quotation explained.*

Constantinople gives to	Uncertain prices.	Certain prices.
London	17 Piaftres	for 1 Pound sterling
Vienna	50 Paras	— 1 Florin
Leghorn	145 Ditto	— 1 Pezza of 8 reals
Genoa	24 Ditto	— 1 Lira fuoribanco
Amsterdam	65 Ditto	— 1 Florin current

Constantinople gives to      Uncertain prices.      Certain prices.

Paris	200 Piaftres	for	300 Francs
Venice	360 Paras	—	{ 1 Sequin of 22 lire
receives from			
Marseilles	{ 1 Franc, 50 centimes }	—	1 Piaftre
Hamburgh	{ 25 Grotos Flemish }	—	1 Ditto
Smyrna	110 Piaftres	—	100 Ditto.

**COPENHAGEN.**

*Monies of Exchange.*

Exchanges are computed in rixdollars, marks, and skillings Danish; and sometimes in rixdollars, marks, and skillings lub or Hamburgh. Pfenings are also sometimes reckoned.

12 Pfenings = 1 Skilling  
 16 Skillings = 1 Mark  
 6 Marks Danish, or 3 marks lub = 1 Rixdollar  
 2 Marks or skillings Danish = 1 Mark or skilling lub.

*Quotation explained.*

Copenhagen gives to	Uncertain prices.	Certain prices.
Amsterdam	143 Rixdollars	for 100 Rixdollars
Hamburgh	149 Ditto	— 100 Ditto
London	{ 6 Rixdollars 30 shillings }	— 1 Pound sterling
Paris	25 Skillings Danish	— 1 Franc.

**DANTZIC.**

*Monies of Exchange.*

Exchanges are computed in florins, groschen, and pfenings.

18 Pfenings = 1 Grosche  
 30 Groschen = 1 Florin or gulden  
 3 Florins = 1 Rixdollar.

*Quotation explained.*

Dantzic gives to	Uncertain prices.	Certain prices.
Amsterdam	372 Groschen	for 1 Pound Flemish
Hamburgh	169 Ditto	— 1 Rixdollar specie
London	24 Florins	— 1 Pound sterling
Paris	110 Rixdollars	— 300 Francs
Francfort	105 Groschen	— 1 Rixdollar.
Leipsic	125 Rixdollars	— 100 Ditto.

**FLORENCE.** See **LEGHORN.**

**FRANCFORT.**

*Monies of Exchange.*

Exchanges are computed in florins and creutzers; or in rixdollars and creutzers; also in florins and batzen.

4 Creutzers = 1 Batze  
 60 Creutzers, or 15 batzen = 1 Florin or gulden  
 90 Creutzers, or 1 $\frac{1}{2}$  florin = 1 Rixdollar of account.

## HAMBURGH.

### *Monies of Exchange.*

Exchanges are computed in marks, schilling lubs, and pfenings; or in pounds, shillings, and pence Flemish; also in rixdollars, marks, &c.

12 Pfenings	= 1 Schilling lubs
16 Schillings	= 1 Mark
3 Marks	= 1 Rixdollar
6 Pfenings	= 1 Grote or penny Flemish
12 Grotes	= 1 Shilling Flemish
20 Grotes Flemish	= 1 Pound Flemish
Thus, 6 Schilling lubs	= 1 Shilling Flemish
7½ Marks	= 1 Pound Flemish.

There are two sorts of money in Hamburg, called *banco* and *currency*. Banco bears an agio or premium against currency, which is generally from 20 to 25 per cent.

### *Quotation explained.*

Hamburg gives to	Uncertain prices.	Certain prices.
London	{ 33 Shillings 7 } for	1 Pound sterling
	{ Grotes Flem. }	
France	26 Schilling lubs —	3 Francs
Spain	91 Grotes Flemish —	1 Ducat of exch.
Portugal	43 Ditto —	1 Old crusade
Genoa	80 Ditto —	1 Pezza of 5½ lire
Leghorn	86 Ditto —	1 Pezza of 8 reals
Bafil	25 Schilling lubs —	1 Ecu of 3 francs
receives from		
Amsterdam	33 Stivers —	2 Marks
Breslau	139 Rixdollars —	100 Rixdollars
Copenhagen	149 Ditto —	100 Ditto
Vienna	310 Florins —	100 Ditto
Venice	82 Soldi piccoli —	1 Mark.

N. B. The exchanges of Hamburg are always transacted in banco, unless otherwise expressed.

## LEGHORN.

### *Monies of Exchange.*

Exchanges are computed in pezze, soldi, and denari di pezza; sometimes in lire, foldi, and denari di lira, moneta buona.

12 Denari di pezza	= 1 Soldo di pezza
20 Soldi di pezza	= 1 Pezza of 8 reals
12 Denari di lira	= 1 Soldo di lira
20 Soldi di lira	= 1 Lira
5¼ Lire, moneta buona	= 1 Pezza of 8 reals.

### *Quotation explained.*

Leghorn gives to	Uncertain prices.	Certain prices.
Vienna	{ 30 Soldi mone- } for	1 Florin
	{ ta buona }	
Novi	186 Pezze —	{ 100 Scudi d'oro marche.

Leghorn

# EXCHANGE.

Leghorn receives from		Uncertain prices.	Certain prices.
Rome	128	Bajocchi for	1 Pezza of 8 reals
Naples	118	Ducats regno	— 100 Ditto
Palermo	11	Tari 15 grani	— 1 Ditto
Genoa	125	Soldi fuori banco	— 1 Ditto
Milan	136	Soldi correnti	— 1 Ditto
Florence	124	Soldi	— 1 Ditto
Turin	93	Soldi	— 1 Ditto
Venice	10½	Lire piccole	— 1 Ditto
France	104	Sous in francs	— 1 Ditto
London	54	Pence sterling	— 1 Ditto
Amsterdam	95	Grotes Flemish	— 1 Ditto
Hamburgh	89	Grotes Flemish	— 1 Ditto
Lisbon	855	Rees	— 1 Ditto
Spain	140	Dollars of plate	— 100 Ditto
Augsburg	204	Florins current	— 100 Ditto
Bologna	96	Bolognini	— 1 Ditto
Ancona	132	Bajocchi	— 1 Ditto
Geneva	109	Ecus of 3 livres	— 100 Ditto
Petersburg	190	Rubles	— 100 Ditto.

LEIPSI. See BERLIN.

## LISBON.

### Monies of Exchange.

Exchanges are computed in rees and milrees, and also in old crusades.

1000 Rees = 1 Milree  
400 Rees = 1 Old crusade.

### Quotation explained.

Lisbon gives to	Uncertain prices.	Certain prices.
Paris	470 Rees	for 3 Francs
Genoa	746 Ditto	— 1 Pezza of 5¾ lire
Leghorn	810 Ditto	— 1 Pezza of 8 reals
Vienna	360 Ditto	— 1 Florin
Venice	66 Ditto	— 1 Lira piccola
Spain	2430 Ditto	— 1 Dobloon of plate
London	66 Pence sterling	— 1 Milree
Amsterdam	45 Grotes Flemish	— 1 Old crusade
Hamburgh	43 Ditto	— 1 Ditto.

## MADRID.

### Monies of Exchange. See CADIZ.

### Quotation of Madrid on Paris explained.

Madrid receives from	Uncertain price.	Certain price.
Paris	{ 15 Francs 40 centimes }	for 1 Dobloon of plate.

The other exchanges of Madrid are similar to those of Cadiz.

## MILAN.

### Monies of Exchange.

Exchanges are computed in lire, soldi, and denari correnti or imperiali.

12 Denari = 1 Soldo  
20 Soldi = 1 Lira  
106 Lire or soldi imperiali = 150 Lire or soldi correnti  
117 Soldi imperiali = 1 Scudo or crown.

### Quotation explained.

Milan gives to	Uncertain prices.	Certain prices.
France	55 Soldi imperiali	for 3 Francs
Genoa	86 Soldi correnti	— 4 Lire fuori banco
Rome	138 Ditto	— 1 Roman crown
Leghorn	135 Ditto	— 1 Pezza of 8 reals
Augsburg	66 Ditto	— 1 Florin current
Venice	84 Ditto	— 1 Ducat current
Vienna	55 Ditto	— 1 Florin current
Amsterdam	57 Ditto	— 1 Florin banco
London	31 Lire correnti	— 1 Pound sterling
Hamburgh	49 Soldi correnti	— 1 Mark.

## NAPLES.

### Monies of Exchange.

Exchanges are computed in ducats and grains, or in ducats, carlins, and grains.

10 Grains = 1 Carlin  
10 Carlins or 100 grains = 1 Ducat regno.

### Quotation explained.

Naples gives to	Uncertain prices.	Certain prices.
Leghorn	120 Ducats regno	for 100 Pezze
Amsterdam	54 Grains	— 1 Florin
Spain	85 Ditto	— 1 Dollar of plate
Rome	125 Ducats	— 100 Roman crowns
Hamburgh	45 Grains	— 1 Mark
Sicily	120 Ditto	— 1 Sicilian crown
London	42 Pence sterling	— 1 Ducat regno
Genoa	102 Soldi fuori banco	— 1 Ditto
Venice	{ 9 Lire 15 soldi piccoli }	— 1 Ditto
France	84 Sous in francs	— 1 Ditto
Lisbon	670 Rees	— 1 Ditto.

## PALERMO.

### Monies of Exchange.

Exchanges are computed in ounces, tari, and grains; and also in scudi, tari, and grains.

20 Grains = 1 Taro  
30 Tari = 1 Ounce  
12 Tari = 1 Scudo or crown;  
Thus 5 Crowns = 2 Ounces.

### Quotation explained.

Palermo gives to	Uncertain prices.	Certain prices.
Amsterdam	5½ Tari	for 1 Florin
Genoa	40 Grains	— 1 Lira fuori banco
Leghorn	12½ Tari	— 1 Pezza of 8 reals
Lisbon	6½ Tari	— 1 Old crusade
London	60 Tari	— 1 Pound sterling
Paris	50 Grains	— 1 Livre
Rome	12½ Tari	— 1 Roman crown
Spain	8½ Tari	— 1 Dollar of plate.
Naples	120 Grains	— 1 Sicilian crown.

## PARIS.

### Monies of Exchange.

Exchanges are computed in francs and centimes; or in livres, sous, and deniers tournois.

100 Centimes

# EXCHANGE.

100 Centimes	=	1 Franc
12 Deniers	=	1 Sou or fol
20 Sous	=	1 Livre
80 Francs	=	81 Livres
3 Livres or 3 francs	=	1 Ecu of exchange.

The 5 franc piece is also sometimes divided into 100 fous, which are distinguished by saying, 100, or so many fous in francs.

### Quotation explained.

Paris gives to	Uncertain prices.	Certain prices.
London	24 Francs	for 1 Pound sterling
Hamburgh	185 Francs	— 100 Marks
Genoa	465 Centimes	— 1 Pezza of 5½ lire
Leghorn	504 Centimes	— 1 Pezza of 8 reals
Spain	15 Francs 40 cent.	— 1 Dobloon of plate
Geneva	162 Francs	— 100 Livres current
Basil	101 Livres	— 100 Livres
Augsburg	249 Centimes	— 1 Florin current
Vienna	160 Centimes	— 1 Florin
Naples	4 Francs 20 cent.	— 1 Ducat regno
receives from		
Amsterdam	54 Grotes Flemish	— 3 Francs
Frankfort	75 Rixdollars cur.	— 300 Ditto
Lisbon	460 Rees	— 3 Ditto
Milan	8 Livres 6 foldi	— 6 Ditto.

### PETERSBURGH.

#### Monies of Exchange.

Exchanges are computed in rubles and copecks.

100 Copecks = 1 Ruble.

### Quotation explained.

Petersburgh gives to	Uncertain prices.	Certain prices.
Constantinople	50 Copecks	for 1 Piafre.
London	28 Pence sterling	— 1 Ruble
Amsterdam	25 Stivers	— 1 Ditto
Vienna	125 Creutzers	— 1 Ditto
Leipfic	17 Groschen	— 1 Ditto
Paris	270 Centimes	— 1 Ditto

### ROME.

#### Monies of Exchange.

Exchanges are computed in scudi moneta, and bajocchi; or in scudi di stampa d'oro, foldi and denari d'oro; quattrini and mezzi quattrini are also sometimes reckoned.

2 Mezzi quattrini	=	1 Quattrino
5 Quattrini	=	1 Bajocco or Bolognino
100 Bajocchi	=	{ 1 Scudo moneta, or Roman crown
1523 Mezzi quattrini, or 1523 <sup>3</sup> / <sub>10</sub> bajocchi	=	{ 1 Scudo di stampa d'oro, or gold crown
12 Denari d'oro	=	1 Soldo d'oro
20 Soldi d'oro	=	1 Gold crown.

### Quotation explained.

Rome gives to	Uncertain prices.	Certain prices.
Florence	84 Gold crowns	for 100 Gold crowns
Milan	81 Roman crowns	— 100 Scudi imperiali
Ancona	99 Ditto	— 100 Crowns
Bologna	98 Ditto	— 100 Ditto
Leghorn	98 Bajocchi	— 1 Pezza of 8 reals
Amsterdam	44 Ditto	— 1 Florin

Rome receives from	Certain prices.	Uncertain prices.
Naples	122 Ducats regno	for 100 Roman crowns
Venice	11 Lire 10 foldi piccoli	— 1 Ditto
Genoa	124 Soldi fuori banco	— 1 Ditto
Paris	105 Sous in francs	— 1 Ditto
London	51 Pence sterling	— 1 Ditto

### ROTTERDAM.

#### Monies of Exchange. See AMSTERDAM.

#### Quotation on London explained.

Rotterdam gives to	Uncertain price.	Certain price.
London	11 Florence current	for 1 Pound sterling.

For the other exchanges of Rotterdam, see AMSTERDAM.

### STOCKHOLM.

#### Monies of Exchange.

Exchanges are computed in rixdollars, skillings, and fenings.

12 Fenings or Oers	=	1 Skilling
48 Skillings	=	1 Rixdollar.

### Quotation explained.

Stockholm gives to	Uncertain prices.	Certain prices.
Amsterdam	44 Skillings	for 1 Rixdollar
Copenhagen	36 Ditto	— 1 Ditto
Dantzic	9½ Ditto	— 1 Florin
Hamburgh	47 Ditto	— 1 Rixdollar
Leghorn	40 Ditto	— 1 Pezza of 8 reals
London	4½ Rixdollars	— 1 Pound sterling
Paris	24 Skillings	— 1 Ecu of 3 livres
Spain	42 Ditto	— 1 Ducat of exch.

### TRIESTE. See VIENNA.

### TURIN.

#### Monies of Exchange.

Exchanges are computed in lire, foldi, and denari.

12 Denari	=	1 Soldo
20 Soldi	=	1 Lira

### Quotation explained.

Turin gives to	Uncertain prices.	Certain prices.
Amsterdam	37 Soldi	for 1 Florin
Augsburg	42 Ditto	— 1 Ditto
Geneva	82 Ditto	— 3 Livres
Genoa	9 Lire 8 foldi	— 1 Sequin
Leghorn	86 Soldi	— 1 Pezza of 8 reals
London	19 Lire 10 foldi	— 1 Pound sterling
Milan	92 Soldi	— 7½ Lire correnti
Paris	20 Lire	— 24 Francs
Rome	87 Soldi	— 1 Roman crown
Venice	94 Ditto	— 1 Ducat current.

### VENICE.

#### Monies of Exchange.

Exchanges are computed in lire, foldi, and denari, moneta piccola; and also in ducats.

12 Denari	=	1 Soldo
20 Soldi	=	1 Lira
6 Lire 4 foldi	=	1 Ducat current, or of account
8 Lire	=	1 Ducat effective

*Quotation*

# EXCHANGE.

## Quotation explained.

Venice gives to	Uncertain prices.	Certain prices.
London	56 Lire piccole	for 1 Pound sterling
Amsterdam	4 Lire 18 foldi ditto	— 1 Florin
Augsburg	4 Lire 16 foldi ditto	— 1 Ditto
Constantinople	3 Lire 6 foldi	— 1 Piaſtre
Paris	2 Lire 5 foldi	— 1 Franc
Genoa	38 Soldi	— 1 Lira fuori banco
Hamburgh	4 Lire 6 foldi	— 1 Mark
Leghorn	11 Lire 18 foldi	— 1 Pezza
Milan	34 Soldi	— 1 Lira corrente
Naples	9 Lire 18 foldi	— 1 Ducat regno
Vienna	4 Lire 8 foldi	— 1 Florin
Rome	12 Lire 10 foldi	— 1 Roman crown.

## VIENNA.

### Monies of Exchange.

Exchanges are computed in florins and creutzers, or in rixdollars and creutzers; pfenings are sometimes used.

4 Pfenings	= 1 Creutzer
60 Creutzers	= 1 Florin
90 Creutzers, or 1½ florin	= 1 Rixdollar of account.

### Quotation explained.

Vienna gives to	Uncertain prices.	Certain prices.
Amsterdam	286 Rixdollars for 100	Rixdollars current
Augsburg	202½ Ditto	— 100 Ditto
Hamburgh	300 Ditto	— 100 Ditto banco
London	19 Florins	— 1 Pound sterling
Paris	47 Creutzers	— 1 Franc
Constantinople	112 Florins	— 1 Piaſtre
Venice	184 Ditto	— 500 Lire piccole
Prague	99½ Ditto	— 100 Florins
receives from		
Genoa	30 Soldi fuori banco	for 1 Florin
Leghorn	28 Soldi moneta buona	— 1 Ditto
Milan	33 Soldi correnti	— 1 Ditto.

## AMERICA.

### Monies of Exchange.

Exchanges are computed in dollars, dimes, and cents; and in some places in pounds, shillings, and pence currency.

10 Cents	= 1 Dime
10 Dimes, or 100 cents	= 1 Dollar,
12 Pence currency	= 1 Shilling ditto
20 Shillings currency	= 1 Pound ditto.

### American Quotations explained.

New York gives to	Uncertain prices.	Certain prices.
London	177 Pounds currency for	1 Pound sterling
Amsterdam	42 Cents	— 1 Guilder
Hamburgh	35 Cents	— 1 Mark
Bremen	78 Cents	— 1 Rixdollar
receives from		
Paris	5 Francs 30 cent.	— 1 Dollar.
Philadelphia gives to		
Amsterdam	43 Cents	for 1 Guilder
Hamburgh	35 Cents	— 1 Mark
receives from		
London	4s. 6d. sterling at par	— 1 Dollar

Vol. XIII.

Baltimore gives to

	Uncertain prices.	Certain prices.
Amsterdam	40 Cents	for 1 Guilder
Hamburgh	33 Cents	— 1 Mark
London	101 Cents	— 4s. 6d. sterling.

These American quotations have been copied from a New York paper of March 1809. All the other quotations may be likewise relied on, having been taken from genuine and recent authorities.

## LONDON.

### Monies of Exchange.

Exchanges are computed in pounds, shillings, and pence sterling; and farthings are sometimes reckoned.

4 Farthings	= 1 Penny
12 Pence	= 1 Shilling
20 Shillings	= 1 Pound.

### Lloyd's List explained.

London gives to	Uncertain prices.	Certain prices.
Madrid	42 Pence sterling for	1 Dollar of plate
Genoa	47½ Ditto	— 1 Pezza of 5¼ lire
Leghorn	51½ Ditto	— 1 Pezza of 8 reals
Lisbon	68 Ditto	— 1 Milree
Naples	42 Ditto	— 1 Ducat regno
Palermo	90 Ditto	— 1 Ounce
receives from		
Amsterdam	34 Shillings Flem.	— 1 Pound sterling
Rotterdam	11 Florins current	— 1 Ditto
Hamburgh	33 Shillings Flem.	— 1 Ditto
Paris	23 Livres 10 fous	— 1 Ditto
Venice	52 Lire piccole	— 1 Ditto
Dublin	{ 10 per cent, that is, 11% Irish }	— 100 Ditto.

Examples for calculating the exchanges of London with the above places are here given; whence the method of computing the exchanges of other places one with another may be easily comprehended, as all operations of this kind may be performed by the Rule of Three Direct.

## LONDON and AMSTERDAM.

English money is reduced to Dutch by saying; as 1l. sterling is to the rate of exchange, so is the given sum to the sum sought.

Reduce 782l. 12s. 6d. sterling to Dutch money, exchange at 34 shillings and 8 pence Flemish per pound sterling.

As	£.	s.	d.	Flem.	::	£.	s.	d.	Flor. Stiv.
	1	:	34	8	::	782	12	6	: 8139 6

				48					
								2,0	16278,6
				145, &c.					Stivers
									8139 Flor. 6 Stiv.
									Dutch

4 N

## EXCHANGE.

Dutch money is reduced to English by reverſing the foregoing operation; thus,

<i>s. d.</i>	<i>£.</i>	Flor. Stiv.	<i>£. s. d.</i>
As 34 8 Flem. :	1 :	8139 6 :	782 12 6

### LONDON and HAMBURGH.

English money is reduced to that of Hamburg by an operation ſimilar to the foregoing.

Reduce 106*l.* 17*s.* 6. ſterling to Hamburg money; exchange at 35 ſhillings 4 grotes Flemiſh *per* pound ſterling.

<i>£. s. d.</i>	<i>£.</i>	<i>s. d.</i>	<i>M. Sc. Pf.</i>
As 1 :	35 4 :	106 17 6 :	1416 1 6
<u>12</u>	<u>20</u>		
424	2137		
<u>6</u>	<u>12</u>		
2544 Pfenings	25650		
<u>2544</u>	<u>2544</u>		

102600	
102600	
128250	
51300	12
<u>24,0)6525360,0</u>	<u>(271890 Pfenings</u>
48	
172, &c.	16)22657 Schill. 6 Pfen.
<u>1416 M. 1 Sc. 6 Pf.</u>	

Hamburg money is reduced to English by reverſing the foregoing operation; thus,

<i>s. d.</i>	<i>£.</i>	<i>M. Sc. Pf.</i>	<i>£. s. d.</i>
As 35 4 Flem. :	1 :	1416 1 6 :	106 17 6

### LONDON and PARIS.

English money is reduced to French by ſaying; as 1*l.* is to the rate of exchange, ſo is the given ſum to the ſum fought.

Reduce 728*l.* 15*s.* ſterling to French money, exchange at 23 livres 10 ſous *per* pound ſterling.

<i>£.</i>	<i>Liv. So.</i>	<i>£. s.</i>	<i>Liv. So. Den.</i>
As 1 :	23 10 :	728 15 :	17125 12 6
<u>20</u>	<u>20 × 470</u>		
470	2,0)685025,0		

<u>2,0)34251,2½</u>	<u>Sous</u>
<u>17125</u>	<u>Liv. 12 Sous, 6 Den.</u>

But if the answer be required in francs, the livres muſt be multiplied by 80 and divided by 81; thus,

<i>Liv. So. Den.</i>	<i>Francs: Cen.</i>
As, 81 :	80 :: 17125 12 6 :
<u>17125 12 6</u>	<u>16914 19</u>

French money is reduced to English by reverſing the foregoing operation; thus,

<i>Francs. Cen.</i>	<i>Liv. So. Den.</i>
As 80 :	81 :: 16914 19 :
<u>16914 19</u>	<u>17125 12 6</u>

And as 23 10 : 1 :: 17125 12 6 : 728 15

The exchange of Paris on London is, however, generally expreſſed in francs, and then the reduction may be performed by a ſingle analogy; thus,

Reduce 4305 francs 95 centimes to ſterling; exchange at 24 francs 25 centimes *per* pound ſterling.

<i>Fr. Cen.</i>	<i>£.</i>	<i>Fr. Cen.</i>	<i>£. s. d.</i>
As 24 25 :	1 ::	4305 95 :	177 11 3½

### LONDON and SPAIN.

English money is reduced to Spanish by ſaying; as the rate of exchange is to 1 dollar, ſo is the given ſum to the ſum fought.

Reduce 391*l.* 1*s.* 3*d.* ſterling to Spanish money, exchange at 35½ ſterling *per* dollar of plate.

<i>d.</i>	<i>Doll.</i>	<i>£. s. d.</i>	<i>Doll. R. M.</i>
As 35½ :	1 ::	391 1 3 :	2643 6 14
<u>2</u>	<u>8</u>	<u>× 20 × 12 × 2</u>	
71	8	187710	
<u>—</u>	<u>34</u>	<u>× 272</u>	
<u>272 Ma. 71)51057120</u>	<u>(719114</u>	<u>Maravedis.</u>	

8)21150 Reals 14 Mar.

2643 Doll. 6 R. 14 M.

But if the answer be required in vellon, the reals of plate ſhould be multiplied by 32 and divided by 17; thus,

<i>Reals. Mar. plate.</i>	<i>Reals. Mar. vell.</i>
As 17 : 32 ::	21150 14 : 39812 18

Spanish money is reduced to English by reverſing the foregoing operation; thus,

<i>Doll.</i>	<i>d.</i>	<i>Doll. R. Mar.</i>	<i>£. s. d.</i>
As 1 :	35½ ::	2643 6 14 :	391 1 3

### LONDON and LEGHORN.

English money is reduced to that of Leghorn by ſaying; as the rate of exchange is to 1 pezza, ſo is the given ſum to the ſum fought.

Reduce 392*l.* 18*s.* 4¼*d.* ſterling to money of Leghorn; exchange at 50¼*d.* *per* pezza of 8 reals.

<i>d.</i>	<i>Pezza.</i>	<i>£. s. d.</i>	<i>Pezza Sol. De.</i>
As 50¼ :	1 ::	392 18 4¼ :	1876 12 5
<u>4</u>	<u>× 20 × 12 × 4</u>		
201	201)377201	(1876 Pez. 12 Sol. 5 Den.	
<u>201</u>	<u>201</u>	<u>&amp;c.</u>	

Money of Leghorn is reduced to English by reverſing the foregoing operation; thus,

<i>Pezza</i>	<i>d.</i>	<i>Pezza Sol. Den.</i>	<i>£. s. d.</i>
As 1 :	50¼ ::	1876 12 5 :	392 18 4¼

### LONDON and GENOA.

English money is reduced to money of Genoa by an analogy ſimilar to the foregoing.

Reduce 239*l.* 11*s.* 3*d.* to money of Genoa; exchange at 45*d.* ſterling *per* pezza of 5¼ lire fuori banco.

<i>d.</i>	<i>Pezza</i>	<i>£. s. d.</i>	<i>Pezza Sol. Den.</i>
As 45 :	1 ::	239 11 3 :	1277 13 4
<u>—</u>	<u>× 20 × 12</u>		

45)57495(1277 Pezze 13 Soldi 4 Den.

45  
124, &c.

But

# E X C H A N G E.

But if the answer be required in lire, the sum thus found should be multiplied by 23, and divided by 4; thus,

Pez. Sol. D. di Pez. Lire Sol. D. di Lira  
As 4 : 23 :: 1277 13 4 : 7346 11 8

Money of Genoa is reduced to English by reverfing the foregoing operation; thus

Lire Sol. D. di Lira Pez. Sol. D. di Pez.  
As 23 : 4 :: 7346 11 8 : 1277 13 4

Pezza d. Pezze Sol. Den. £. s. d.  
And as 1 : 50 $\frac{1}{2}$  :: 1277 13 4 : 239 11 3

## LONDON and LISBON.

English money is reduced to Portuguese by faying; as the rate of exchange is to 1 milree, fo is the given fum to the fum fought.

Reduce 218*l.* 8*s.* 5 $\frac{1}{2}$ *d.* to Portugal money; exchange at 63 $\frac{1}{2}$ *d.* sterling *per* milree.

d. Milree £. s. d. Mil. Rees  
As 63 $\frac{1}{2}$  : 1 :: 218 8 5 $\frac{1}{2}$  : 827 160  
8 × 20 × 12 × 8

507 507)419370(827,160  
4056

&c.

Portugal money is reduced to English by reverfing the foregoing operation; thus,

Milree d. Mil. Rees £. s. d.  
As 1 : 63 $\frac{1}{2}$  :: 827 160 : 218 8 5 $\frac{1}{2}$

## LONDON and NAPLES.

English money is reduced to that of Naples by faying; as the rate of exchange is to 1 ducat, fo is the given fum to the fum fought.

Reduce 158*l.* 9*s.* 3*d.* to money of Naples; exchange at 37 $\frac{1}{2}$ *d.* sterling *per* ducat regno.

d. Ducat £. s. d. Ducats Grains  
As 37 $\frac{1}{2}$  : 1 :: 158 9 3 : 1014 16

	787	15	0 English.

### Arbitration of Exchange.

Arbitration of exchange is a comparison between the courses of exchange of several places in order to ascertain the most advantageous method of drawing or remitting bills. It is distinguished into simple and compound arbitration; the former comprehends the exchanges of three places only, and the latter of more than three places.

#### Simple Arbitration

It is a comparison between the exchanges of two places with respect to a third; that is to say, it is a method of finding such a rate of exchange between two places, as shall be in proportion with the rates quoted between each of them and a third place. The exchange thus determined, is called the *arbitrated price*, and also *proportional exchange*; and the *proportional par*.

If, for example, the course between London and Paris be 24 francs for 1l. sterling, and between Paris and Amsterdam 54d. Flemish for 3 francs, (that is, 36s. Flemish for 24 francs,) the arbitrated price between London and Amsterdam, through Paris, is evidently 36s. Flemish for 1l. sterling: for as 3 fr. : 54d. Flem. :: 24 fr. : 36s. Flem.

Now when the actual direct price (as seen by a quotation or otherwise advised,) is found to differ from the arbitrated price, advantage may be made by drawing or remitting indirectly, that is, by drawing on one place through another, as on Amsterdam through Paris; which may be performed in three different ways.

1st. London may draw on Paris, and order his correspondent there to draw on Amsterdam.

2d. London may draw on Paris, and order his correspondent in Amsterdam to remit the same sum to Paris.

3d. London may order his correspondent at Paris to draw on Amsterdam, and to remit the value to London.

The operation of remitting indirectly, or of remitting to one place through another, may be likewise performed in three different ways:

1st. London may remit to Paris, and order his correspondent there to remit the sum to Amsterdam.

2d. London may remit to Paris, and order his correspondent in Amsterdam to draw on Paris.

3d. London may take bills on Paris, and remit them to Amsterdam, there to be negotiated.

To exemplify this by familiar illustrations, suppose the arbitrated price between London and Amsterdam to be as before stated, 36s. Flemish for 1l. sterling; and suppose the direct course, as given in Lloyd's list, to be 37s. Flemish, then London, by drawing directly on Amsterdam, must give 37s. Flemish for 1l. sterling; whereas, by drawing through Paris, he will give only 36s. Flemish for 1l. sterling: it is therefore the interest of London to draw indirectly on Amsterdam through Paris.

On the contrary, if London remits directly to Amsterdam, he will receive 37s. Flemish for 1l. sterling; whereas, by remitting through Paris, he will receive only 36s. Flemish: it is the interest of London therefore to remit directly to Amsterdam.

*Example 2.*—Suppose the exchange of London on Lisbon to be at 68d. per milree, and that of Lisbon on Madrid 500 rees per dollar, the arbitrated price between London and Madrid is 34d. st. per dollar; for as 1000 rees : 68d. :: 500 rees : 34d. But if the direct exchange of London on Madrid be 35d. sterling per dollar, then London, by remitting directly to Madrid, must pay 35d. for every dollar; whereas by remitting through Lisbon he will pay only 34d.: it is therefore the interest of London to remit indirectly to Madrid through Lisbon.

On the contrary, if London draws directly on Madrid, he will receive 35d. sterling per dollar; whereas, by drawing indirectly through Lisbon, he would receive only 34d.: it is therefore the interest of London to draw directly on Madrid.

From these examples, the two following rules are manifest.

*Rule 1.*—Where London gives the certain price, draw through that place which gives the lowest arbitrated price, and remit through that which produces the highest.

*Rule 2.*—Where London gives the uncertain price, draw through that place which produces the highest arbitrated price, and remit through that which gives the lowest.

What is said here of London will equally apply to any other place from whence the operation is made.

Suppose the exchange of London on Amsterdam to be 34.6; on Genoa, 47; on Leghorn, 52; and the exchange of Amsterdam on Genoa, 86; on Leghorn, 93; what is the most advantageous method for London to remit to, or draw on Amsterdam?

1st.—Because 47d. st. give 1 pezza in Genoa, and this pezza in Amsterdam gives 86d. Flemish, say, as 47d. st. : 86d. Flemish :: 240d. st. : 439d. Flemish, or 36s. 7d. Flemish, which is the arbitrated price through Genoa.

2d.—Because 52d. st. give 1 pezza in Leghorn, and this pezza in Amsterdam gives 93d. Flemish, say, as 52d. st. : 93d. Flemish :: 240d. st. : 429d. Flemish, or 35s. 9d. Flemish, which is the arbitrated price through Leghorn.

Hence, according to the first rule, the interest of London is to draw directly on Amsterdam, instead of drawing through Genoa or Leghorn; and to remit through Genoa, instead of remitting directly to Amsterdam, or indirectly through Leghorn.

And according to the second rule, the interest of Amsterdam would be to remit directly to London, and to draw on London through Genoa.

*Compound*

# EXCHANGE.

## Compound Arbitration:

Is a comparison between the exchanges of more than three places in order to find how much a remittance passing through them all will amount to at the last place, or to find the arbitrated price between the first place and the last, and thus to determine on the most advantageous mode of negotiating bills.

Compound arbitration is therefore a repetition of simple arbitration, and may be solved by a continuation of several statings in the Rule of Three; but all such operations are best performed by conjoint proportion; commonly called the "Chain rule," which shall be here explained and demonstrated, after giving an example of compound arbitration by the Rule of Three.

Suppose the exchange between London and Amsterdam to be 35 shillings Flemish for 1 l. sterling; between Amsterdam and Lisbon, 42 pence Flemish for 1 old crusade; and between Lisbon and Paris, 480 rees for three francs, what is the arbitrated exchange between London and Paris?

1st. As 35s. Flem. : 1 l. :: 42d. Flem., or 3½s. Flem. : 2s. ft. = 1 old crusade.  
 2dly. As 1 old crusade, or 400 rees : 2s. ft. :: 480 rees : 2s. 4¾d. ft. = 3 francs.  
 3dly. As 2s. 4¾d. ft. : 3 francs :: 240d. ft. : 25 francs.  
 Hence the arbitrated price is 25 francs for 1 l. sterling.

### The Chain Rule explained and demonstrated.

Distinguish the several courses of exchange into antecedents and consequents, and place them in two columns, the antecedents to the left and the consequents to the right, by way of equation.

The first antecedent must be of the same denomination as the quantity of which the value is required.

The first consequent must be of the same denomination as the second antecedent, and the second consequent as the third antecedent; and so on throughout.

The last consequent must be of that denomination in which the answer is required.

The terms being thus arranged, the antecedents must be multiplied continually for a divisor, and the consequents for a dividend; and the quotient will be the answer.

The calculation may be abridged by expunging such antecedents and consequents as are alike, and reducing such their lowest terms as admit of a common divisor.

### Example from the foregoing Question.

1 l. Sterling = 35 Shillings Flemish.  
 3½ Shillings Flemish = 400 Rees  
 480 Rees = 3 Francs.  
 How many francs will 1 l. sterling give?

$$\frac{3 \times 400 \times 35}{1 \times 480 \times 3\frac{1}{2}} = \frac{42000}{1680} = 25 \text{ francs.}$$

In this example, 480 and 400 have the common divisors 8 and 10, and they may therefore be reduced to 5 and 6; again the antecedent 6 may be reduced to 2, by striking out the first consequent 3; the fraction is therefore reduced

$$\text{to } \frac{5 \times 35}{2 \times 3\frac{1}{2}} = \frac{175}{7} = 25, \text{ as before.}$$

### Demonstration of the Chain Rule.

Let A, B, C, D, &c. be several denominations of money, and m, n, p, q, &c. the numbers or quantities of those denominations, and let them stand thus:

Antecedents.	=	:	:	Consequents.
m A . . .	=	:	:	n B
p B . . .	=	:	:	q C
r C . . .	=	:	:	s D
t D . . .	=	:	:	v E

Now to find what number of the last denomination (E) is equal to a given number of the first denomination (A) let z times the last term = y times the first, that is, let z E = y A.

Multiply all these equations together, the antecedents by the antecedents, and the consequents by the consequents, which will give m A × p B × r C × t D × z E = n B × q C × s D × v E × y A, and this equation reduced is m p r t z = n q s v y.

Now if the number of the last denomination be required, z =  $\frac{n q s v y}{m p r t}$ ; but if the number of the first denomination

be required, y =  $\frac{m p r t z}{n q s v}$ . Q. E. D.

Example 2.—If London remit 1000 l. sterling to Cadiz by way of Holland at 35 s. Flemish per pound sterling; thence to France at 58 d. Flemish per ecu of 3 francs; and thence to Cadiz at 15½ francs per doubloon of 4 dollars, what is the price between London and Cadiz resulting from the operation? and how many dollars will the 1000 l. amount to in Spain?

1 Pound sterling	=	35 Shillings Flemish
1 Shilling Flemish	=	12 Pence Flemish
58 Pence Flemish	=	3 Francs
15½ Francs	=	1 Doubloon
1 Doubloon	=	4 Dollars

How many dollars are equal to 1000 l. sterling?

$$\frac{35 \times 12 \times 3 \times 4 \times 1000}{58 \times 15\frac{1}{2}} = \frac{5040000}{899} = 5606 \text{ dollars, 1 real,}$$

28 mar. which gives the exchange at 42¾ d. nearly.

The indirect course of exchange between London and Cadiz may be also found by an inverse operation, called the *Doctrine of Contraries*: thus,

4 Dollars	=	1 Doubloon
1 Doubloon	=	15½ Francs
3 Francs	=	58 Pence Flemish
12 Pence Flemish	=	1 Shilling Flemish
35 Shillings Flemish	=	240 Pence sterling.

How many pence sterling equal 1 dollar?

$$\frac{240 \times 58 \times 15\frac{1}{2}}{4 \times 3 \times 12 \times 35} = \frac{58 \times 15\frac{1}{2}}{3 \times 7} = \frac{899}{21} = 42\frac{1}{2} d.$$

Now if the direct course of exchange was above the indirect, the circular remittance would be most advantageous; but if under, the direct operation would be preferable.

In computing the profits or losses of exchange operations, allowance should be made for the expences, commission, and interest of money, all of which may be comprised in the statement by the Chain Rule; that is, by deducting them from those terms of the consequents to which they may relate; thus, in the following example, the *per centage* is subtracted from 100 in the last place of the consequents.

Example 3.—London takes bills on Madrid at 33½ d. per dollar of exchange, remits them to Amsterdam, with orders to negotiate at 90½ grotes per ducat of exchange, and make the returns in bills on Paris at 51½ grotes per ecu of 3 francs: what does London gain or lose per cent. by this operation, supposing the bills on Paris are negotiated at 25 livres 18 sous per pound sterling; and that all the charges, including interest for the time that London is out of its money, amount to 1½ per cent.?

$$33\frac{1}{2} \text{ Pence sterling} = 272 \text{ Maravedis}$$

$$125 \quad 278 \text{ Maravedis} = 90\frac{1}{4} \text{ Grotes}$$

## EXCHANGE.

51½ Grotes = 2 Francs  
 4 \$5 Francs = 81 Livres  
 1 Livre = 20 Sous  
 259 51½ Sous = 440 Pence sterling 120  
 100 Pence sterling = 98½ On account of charges.  
 How much does 100*l.* sterling give?

$$\frac{272 \times 90\frac{1}{2} \times 81 \times 99\frac{1}{2}}{33\frac{1}{2} \times 125 \times 51\frac{1}{2} \times 4 \times 259 \times 100} = 105,853, \text{ answer.}$$

The profit is therefore *5l. 17s. 0½d. per 100*l.* sterling.*

Operations in compound arbitration may be greatly facilitated by the help of logarithms: thus, "from the sum of the logarithms of the consequents, subtract the sum of the logarithms of the antecedents; the difference will be the logarithm of the answer."

In this case, however, the reduction of the numbers as above is superfluous, as it is as easy to find the logarithm of a large as of a small number; but when equal terms are on both sides they should be struck out; and if a common divisor can be found which will reduce any term to unity, it will likewise shorten the operation.

In questions of this kind much time and labour may be sometimes saved by making use of *fixed numbers*; thus, where several terms are unchangeable in both the antecedents and consequents they can be reduced to one; and the constant logarithm of this number may be used with those that vary; such as the logarithms of the rate of exchange, the amount of the charges, &c.

Besides the foregoing rules for facilitating the arbitration of exchange, various other methods have been proposed for shortening and illustrating the subject; even triangles and other diagrams have been constructed for this purpose; (see Postlethwait's Commercial Dictionary, vol. i. p. 94.) but geometrical projections do not seem well adapted to elucidate this rule.

A graphic operation, however, of a very useful and ingenious description, has been lately executed in London, in which scales of the monies of exchange of the principal places in Lloyd's list are so graduated and arranged, that the arbitrated price between any two of them, with respect to a third place, may be immediately found by the application of a right line. The invention is by William Wollaston, M.D. S. and F.R.S.

We shall conclude this article by giving rules for calculating the intrinsic par of exchange, and also tables of the same in gold and silver according both to mint regulations, and to assays.

The intrinsic par of exchange may be calculated by the rules laid down for computing the value of coins. (See COIN.) But the operation may be performed with greater precision by the Chain rule, as in the following examples.

*Example 1.*—What is the intrinsic par between London and Lisbon, in *gold*, when taken from the Johanes of 6400 rees, which, according to the mint regulations of Portugal, contains 221½ grains of English standard gold?

6400 Rees = 221½ Grains of standard gold  
 480 Grains stand- } = 934½ Pence sterling.  
     ard gold }

How many pence sterling will 1000 rees give?

$$\text{Striking out the common divisor } 1000, \frac{221\frac{1}{2} \times 934\frac{1}{2}}{64 \times 48} =$$

69,35*d.* sterling for the milree.

*Example 2.*—What is the intrinsic par between London and Madrid, in *silver*, the weight of the dollar being 17 dwt. 8 gr. Troy, and its fineness 8 dwt. worse

than English standard, according to average assays lately made at his majesty's mint at the Tower of London.

85 Dollars of exchange = 64 Hard dollars  
 1 Hard Dollar = 416 Grains Troy  
 222 Grains in dollars = 214 Grains standard  
 480 Grains standard = 62 Pence sterling.

How many pence sterling does 1 dollar of exchange give?

$$\text{Striking out the common divisor } 64, \frac{416 \times 214 \times 62}{85 \times 111 \times 15} = 39\frac{1}{2} \text{d. sterling for the dollar of exchange.}$$

*Example 3.*—What is the intrinsic par between London and Amsterdam, in *silver*, when taken from the rixdollar current, which weighs 18 dwt. Troy, and is (according to assays) 16 dwt. worse than English standard, taking the agio of banco on currency at 4 per cent.

62 Pence sterling = 20 Dwt. standard silver  
 202 Dwt. standard = 222 Dwt. in rixdollars  
 18 Dwt. or 1 rixdollar = 50 Stivers currency  
 1 Stiver = 2 Grotes  
 12 Grotes = 1 Shilling Flemish  
 104 Shillings Flemish } = { 100 Shillings Flemish  
     currency }                      banco.

How many shillings Flemish banco do 240 pence sterling give?

*Brought down and reduced.*

31	6½	20	5
103	108	111	37
5	13	50	50
13	104	100	25
		110	20

$$\frac{5 \times 37 \times 50 \times 25 \times 20}{31 \times 103 \times 3 \times 13} = 37\frac{1}{2} \text{d. Flemish for the pound sterling.}$$

From the two foregoing tables it appears, that the par in gold generally varies from that in silver, and in some places very considerably.

It also appears that the assays do not differ essentially from the mint regulations; but where any difference is found to exist, it is mostly in deficiency.

The intrinsic par of exchange between any other places, besides the above, may be determined by the foregoing rules, and from the money tables in the present article, with those given in the article COIN.

It should be observed, that in the calculation of the par for Amsterdam, the ducat is reckoned at 5 florins 5 stivers currency, but this price is subject to alteration, and therefore no permanent par in gold can be established with Holland, even if the agio were fixed. It should be also remarked, that in computing the par with Hamburgh the ducat is reckoned at 6 marks Hamburgh banco, and the Cologne mark of fine silver at 27½ marks banco, which are the common, but not constant prices, and therefore no permanent par can be established with Hamburgh, any more than with Amsterdam.

Authors on exchange are very numerous, though few can be mentioned that have produced full and accurate systems: the principal are, Kruse of Hamburgh; Ricard of Amsterdam; Gerhardt of Berlin; Marien of Spain; Senebier of Geneva; Giraudeau, Kuelle, Reishammer, and Corbaux of France; and Duboit of London. Among the productions of those writers Kruse's Hamburgh Contorist has been the most universally approved; an English translation of this system of exchanges, monies, weights and measures, with considerable additions and alterations, is now nearly printed, and will be shortly published, under the title of the "Universal Cambist;" from which the present article has been chiefly extracted.

EXCHANGE also denotes a public place, in most considerable cities, wherein the merchants, negociants, agents, bankers, brokers, interpreters, and other persons concerned in commerce, meet, on certain days, and certain times thereof, to confer, and treat together of matters relating to exchanges, remittances, payments, adventures, assurances, freights, and other mercantile negotiations both by land and sea.

In Flanders, Holland, and several cities of France, these places are called *bourses*; at Paris and Lyons, *places de change*; and in the Hanse towns, *colleges of merchants*.

These assemblies are held with so much exactness, and merchants and negociants are so indispensably required to attend at them, that a person's absence alone makes him be suspected of a failure or bankruptcy.

The most considerable exchanges in Europe are that of Amsterdam, and that of London, called the Royal Exchange. For an account of the latter, see ROYAL EXCHANGE.

The former is a large building, 230 feet long and 130 broad, round which runs a peristyle or portico, 20 feet wide. The columns of the peristyle, amounting to 46, are numbered, for the convenience of finding persons.

That of Antwerp was little inferior to either of them, till a variety of circumstances concurred to effect its ruin, and to transfer its trade to Amsterdam; the era of this important event in commercial history is about the year 1585.

Even in the time of the ancient Romans there were places for the merchants to meet, in most of the considerable cities of the empire. That said by some to have been built at Rome in the year of the city 259, 493 years before our Saviour, under the consulate of Appius Claudius and Publius Servilius, was called *collegium mercatorum*; whereof it is pretended there are still some remains, called by the modern Romans *loggia*, the lodge; and now, usually the "Place of St. George."

This notion of a Roman exchange is supposed to be founded on the authority of Livy, whose words are as follow; viz. "Certamen consulibus inciderat, uter dedicaret Mercurii ædem. Senatus a se rem ad populum rejecit utri eorum dedicatio jussu populi data esset, eum præesse annonæ, mercatorium collegium instituire jussit." Liv. lib. ii. But it must be here remarked, that *collegium* never signified a building for a society in the purer ages of the Latin tongue; so that "collegium mercatorum instituire" must not be rendered to build an exchange for the merchants, but to incorporate the merchants into a company. As Mercury was the god of traffic, this ædes Mercurii seems to have been chiefly designed for the devotions of this company or corporation.

EXCHANGE, in Law, is a mutual grant of equal interests in lands or tenements, the one in consideration of the other; and in our common law it more particularly denotes the compensation which the warrantor must make the warrantee, value for value, if the land warranted be recovered from the warrantee. Bracton, lib. ii.

The word "exchange," is so individually requisite and appropriated by law to the case now stated, that it cannot be supplied by any other word, or expressed by any circumlocution. (Co. Litt. 50, 51.) The estates exchanged must be equal in quantity (Litt. § 64, 65.), not of value, for that is immaterial, but of interest; as fee-simple for fee-simple, a lease for 20 years for a lease of 20 years, and the like. And the exchange may be of things that lie either in grant or in livery. (Co. Litt. 51.) But no livery of seisin, even in exchanges of freehold, is necessary to perfect the conveyance

conveyance (Litt. § 62.); for each party stands in place of the other and occupies his right, and each of them hath already had corporal possession of his own land. But entry must be made on both sides; for, if either party die before entry, the exchange is void for want of sufficient notoriety. (Co. Litt. 50.) And so also, if two persons, by consent of patron and ordinary, exchange their preferments; and the one is presented, instituted, and inducted, and the other is presented, and instituted, but dies before induction; the former shall not keep his new benefice, because the exchange was not completed; and therefore he shall return back to his own. (Park, § 288.) For if, after an exchange of lands or other hereditaments, either party be evicted of those, which were taken by him in exchange, through defect of the other's title, he shall return back to the possession of his own, by virtue of the implied warranty contained in all exchanges. Blackst. Comm. book ii. See WARRANTY.

EXCHANGE of goods and chattels. See SALE.

EXCHANGE, *the king's*, is the place appointed by the king for exchange of plate, or bullion for the king's coin. These places have formerly been diverse: but now there is only one, *viz.* that of the Tower of London, joined with the Mint.

EXCHANGE, *bill of*. See BILL of Exchange.

What we call re-exchange, is the due, or premium of a second exchange, when a bill is protested. See RE-EXCHANGE.

EXCHANGE brokers. See Exchange BROKERS.

EXCHANGE of Prisoners. This measure, which is dictated both by humanity, and, in general, by mutual interest, is frequently adopted by two hostile nations, for the purpose of easing themselves from the great charge incurred by the retention of prisoners of war in prisons, depots, &c. Sometimes an exchange becomes a consideration while drawing up the articles of a capitulation; especially where the besiegers consider it a matter of policy to get possession of a fortress, without being too strict in the conditions of surrender.

Thus we frequently observe, that a garrison is allowed to retire, under the express stipulation, that "no part thereof shall serve again until regularly exchanged." In such case, an immediate liberation of an equal number of those confined in the enemy's prisons ought instantly to take effect, and the persons thus discharged should be forwarded to their country; but if, as sometimes occurs at the very commencement of a war, when one party has been extensively successful, the other may not have the means of equalization in regard to the liberation of prisoners, it may occur, that months, or even years, may elapse, before such restriction may be removed.

This, indeed, is not the only point on which the matter may rest: it may sometimes happen, that a prince may feel it to be his interest not to carry an exchange into effect; and this he may justify under the ordinary circumstances attendant upon capitulation. Say, that an army surrenders simply under this condition; "that it shall not serve until duly exchanged." Here we see no obligation on the part of its superiors to make any exchange: therefore, when policy dictates such forbearance, we cannot affix any imputation on the prince, power, &c., if no exchange takes place.

If, indeed, the garrison are allowed to return to their country, or to retire unmolested, on condition that "they shall be exchanged," then, we naturally expect, that no time will be lost in liberating an equal number; diverting to the several classes of those allowed to retire, and pairing them off in a correct manner.

We have heard of evasions contrived for the express pur-

pose of detaining some individual, who, by his prowess, or abilities, may have become highly obnoxious to the enemy. This, however, can only take place where there is no person of corresponding rank, against whom he can be paired off; then the exchange necessarily becomes in a degree arbitrary; though it is a matter of courtesy, to form some equivalent, in such manner as may suit the wishes of his own government.

With a view to facilitate the exchanges occasionally ordered, as well as to obviate the million of frivolous complaints which would else be made, it is customary for powers at war either to receive agents, or to appoint supervisors, whose duty is confined solely to such matters as relate to the due subsistence of the prisoners, and to conducting whatever may relate to exchanges. Through this medium a government may always avail itself of the means of releasing any particular persons, confined as prisoners of war in the enemy's country; but, to effect this, at least to be able to command it, there must be in its power some equivalent: for it would be unreasonable to expect that a general officer should be given up, when only a colonel could be offered in exchange; but a general may be liberated by any government, for the purpose of liberating any officer of inferior rank then in the power of the enemy: and so throughout.

EXCHANGERS are those who return money beyond sea, by bills of exchange, &c. called anciently also *excambiators*, and since *remitters*.

EXCHEQUER, or simply *Chequer*, originally denotes a chess-board; or a frame divided into sixty-four squares, of two colours, whereon to play at draughts, chess, &c. See CHESS, &c.

The word is formed from the French *eschiquier*, which signifies the same. Hence, trees are said to be planted chequer-wise, in *quincunx*, when disposed so as to form diverse squares representing a chequer.

EXCHEQUER is more particularly used for a chamber, or apartment, in Westminster-hall, consisting of two parts; the court of exchequer and the lower exchequer. See COURT of Exchequer, and COURT of Exchequer-chamber.

EXCHEQUER-bills are a species of paper first established by Mr. Montague, in 1696, as a more convenient kind of security than the tallies and orders for repayment then in use, and also to supply the want of circulating cash, during the re-coinage at that period. They were then taken at the exchequer for all payments of the revenue, and, when re-issued, they were allowed 7l. 12s. per cent. interest. They have since been issued yearly for anticipating the produce of particular taxes; and they have almost constantly formed the principal article of that part of the public debt called the unfunded debt. Of late years the total amount of outstanding exchequer bills (exclusive of those charged on specific branches of the revenue) has usually been about 12 millions. The bank of England, ever since the year 1706, have been the contractors for their circulation, at a certain premium. The commissioners of the treasury are empowered, by various statutes, to borrow money, within a specific sum, limited by those statutes, by issuing exchequer bills on the credit of certain duties; which bills, by 12 Anne, cap. 11. and 12 Geo. I. cap. 11. bear an interest of 2d. a day per cent. payable to the bearers. But the interest payable on them has differed according to the current rate of interest at the time when they have been issued. Those now in circulation bear interest at the rate of 3½d. a day per cent. They are often made for 100l. each, but of late years they have been chiefly for 1000l. each, and sometimes for larger sums. These bills are numbered arithmetically,

cally, and registered accordingly, so that the principal sums may be paid off in course, the time of which is notified by public advertisement. The said exchequer bills shall be current to all receivers and collectors of the customs, excise, or any revenue, and at the receipt of the exchequer; and as any of them are paid or lent into the exchequer, the officers there shall cause tallies to be levied and delivered to the payers or lenders, as if they had made such payments or loans in specie. The instalments on loans are paid into the receipt of the exchequer in exchequer bills, which are received again by the bank as cash, either for the amount of dividends due, or in repayment of advances. When these bills are sold at a considerable discount, or any other circumstance indicates that too many of them are in circulation, it is usual to fund a part of them, that is, to convert them into a permanent debt by offering the holders of them stock in lieu of their bills. This of late has been frequently done. The total amount of exchequer bills issued for the public service between the 5th of January 1808 and the 5th of January 1809, and not redeemed within that period, was 39,735,200*l.* The unfunded debt in exchequer bills, outstanding on the 5th of January 1809, was 40,093,200*l.* The amount of exchequer bills issued for the public service in Ireland, between the 5th of January 1808 and the 5th of January 1809, and not redeemed within that period, was 541,666*l.* 13*s.* 4*d.* If any exchequer bills be lost, upon affidavit before a *baron* of the exchequer, and certificate from him, and security given to pay the same if found, duplicates are to be made out; and when bills are defaced new ones shall be delivered. Forging of these bills, or of the indorsements on them, is felony.

EXCHEQUER, *messenger of the.* See MESSENGER.

EXCHEQUER, *Black Book of the,* is a book under the keeping of the two chamberlains of the exchequer; said to have been composed in 1175, by Gervaise of Tilbury, nephew of king Henry II. and divided into several chapters.

Herein is contained a description of the court of England, as it then stood, its officers, their ranks, privileges, wages, perquisites, powers, and jurisdiction; and the revenues of the crown, both in money, grain, and cattle. Here we find, that for one shilling, as much bread might be bought as would serve a hundred men a whole day; that the price for a fat bullock was only twelve shillings, and a sheep four, &c. Larrey, p. i. p. 394. See also DOMESDAY.

EXCISE, an inland duty, or imposition, charged on commodities of general consumption, and paid sometimes upon the consumption of the commodity, or frequently upon the retail sale, which is the last stage before the consumption. This mode of taxation was adopted among the Romans; for Augustus, after the civil wars, introduced an excise, which, though very moderate, was general. It seldom exceeded one *per cent.* but it comprehended whatever was sold in the markets or by public auction, from the most considerable purchases of lands and houses, to those minute objects which can only derive a value from their infinite multitude and daily consumption. Such a tax, however, as it affects the body of the people, has ever been the occasion of clamour and discontent. Augustus was obliged to declare by a public edict, that the support of the army depended in a great measure on the produce of the excise; and Tiberius diminished the excise to one-half, though the relief was of very short duration. It has been adopted, in more modern times, as the most economical mode of taxing the subject; the charges of laying, collecting, and managing the excise duties being considerably less in proportion than in other branches of the revenue. Besides, it renders the commodity cheaper to

the consumer than charging it with customs to the same amount would do, because this tax is generally paid in a much later stage of it. Nevertheless, the rigour and arbitrary proceedings of excise-laws seem hardly compatible with the temper of a free nation. For the frauds that might be committed in this branch of the revenue, unless a strict watch is kept, makes it necessary, wherever it is established, to give the officers a power of entering and searching the houses of such as deal in exciseable commodities, at any hour of the day, and, in many cases, of the night likewise. And the proceedings in case of transgressions are so summary and sudden, that a man may be convicted in two days' time in the penalty of many thousand pounds by two commissioners or justices of the peace; to the total exclusion of the trial by jury, and disregard of the common law. Obnoxious as the excise duty has always been, it was first suggested by the earl of Bedford, lord treasurer to king Charles I., but never actually introduced in that prince's reign. Its original establishment took place in the year 1643, when it was introduced, on the model of the Dutch prototype, by the long parliament after its rupture with the crown; and its progress has been gradual. It was at first laid upon those persons and commodities, where it was supposed the hardship would be least perceivable, *viz.* the makers and venders of beer, ale, cyder, and perry; and though it originated with the long parliament, the royalists at Oxford soon followed the example of their brethren at Westminster, by imposing a similar duty; both parties, however, protesting that it should be continued no longer than to the end of the war, and then be utterly abolished. But the parliament at Westminster soon after imposed it on flesh, wine, tobacco, sugar, and such a multitude of other commodities, that it might be fairly denominated general. This was done in pursuance of the plan laid down by Mr. Pymme, who had been intended for chancellor of the exchequer under the earl of Bedford, and who seems to have been the father of the excise. In his letter to sir John Hotham (30 May, 1643) he intimates, "that they had proceeded in the excise to many particulars, and intended to go on farther; but that it would be necessary to use the people to it by little and little." Having accustomed the people to it for some years, the succeeding champions of liberty boldly and openly declared (Ord. 14th August, 1649, ch. 50.) "the impost of excise to be the most easy, and indifferent levy that could be laid upon the people;" and accordingly it was continued during the whole usurpation. Upon the restoration of king Charles II., as it had been long established, and its produce was well known, some part of it was given to the crown, in 12 Car. II., by way of purchase for the feudal tenures and other oppressive parts of the hereditary revenue. (See REVENUE.) Notwithstanding its general unpopularity, it has been imposed on abundance of other commodities in the reigns of king William III. and of every succeeding prince, towards supporting the enormous expences occasioned by our wars on the continent. In the year 1732, the gross produce of the excise-duty amounted to 2,964,617*l.* About this time sir Robert Walpole, being of opinion, that taxes on consumable commodities, to which every citizen contributes in proportion to his consumption, and which, being included in the price of the commodity, are insensibly paid, constituted the most eligible mode of raising the revenue necessary for the public service, formed a project for the gradual abolition, not only of the taxes on land, houses, and windows, but also of the customs, by the substitution of productive excise duties. Fully apprized of the abuses and frauds to which the collection of the customs was subject, and which he had no hope of remedying, he thought that the scheme of convert-

## EXCISE.

ing the greater part of the customs into duties of excise, would be equally advantageous to government and to the fair trader; and that the excise laws might be so ameliorated, that, notwithstanding the odium generally attached to them as arbitrary, and oppressive, no just ground of complaint should remain. With a view to the execution of this plan, he obtained a revival of the salt-duties, which had been repealed some years before; but upon proposing, in the following year, to transfer the duties on wine and tobacco to the excise, "faction," says Dr. Smith (*Wealth of Nations*, vol. iii. p. 358.) "combined with the interest of smuggling merchants, raised so violent, though unjust a clamour against that bill, that the minister thought proper to drop it." The defeat of this scheme was celebrated by general rejoicings, as a deliverance from the greatest political danger.

The several commodities now subject to excise duties are ale, beer, cyder, perry, mum, metheglin, and mead; things sold by auction; bricks and tiles; candles; coaches and coach-makers; coffee, tea, chocolate, and cocoa-nuts; glass; hops; leather; linen cloths, silks, cottons, and calicoes; malt; paper; plate; salt; soap; spirituous liquors; starch, hair-powder, and stone-blue; sweets; tobacco and snuff; vinegar and verjuice; wine; and wire. See each of these articles.

In the year 1787 the various rates of duty which had been imposed at different times were consolidated; and other regulations were also adopted, by which the produce of the revenue was augmented, and the expence of collecting it materially reduced.

By 24 Geo. II. c. 40, all fines, penalties, and forfeitures, imposed by this or any other act relating to the duties of excise, shall be sued for, levied, recovered, or mitigated by such ways and means as any fine, penalty, or forfeiture is or may be recovered or mitigated by any law or laws of excise, or in the courts at Westminster, and shall be half to the king and half to him that shall inform or sue:—that is to say, if within the limits of the chief office in London, the offence shall be determined by the commissioners (or any three of them, 1 Geo. II. st. 2. c. 16.) or, in case of appeals, by the commissioners of appeals; in all other places they shall be heard and determined by any two or more justices of the peace, residing near the place where the offence was committed, or forfeiture incurred; and in case of neglect or refusal of such justices, for the space of fourteen days next after complaint made, and notice thereof given to the offender; then the sub-commissioners may hear and determine the same; and if the party find himself aggrieved by the judgment given by the said sub-commissioners, he may appeal to the next quarter-sessions, whose judgment therein shall be final. The said commissioners for appeals, and chief commissioners for excise, and all justices of the peace and sub-commissioners aforesaid, are required, upon any complaint or information exhibited of any such forfeiture made or offence committed, to summon the party accused, and upon his appearance or contempt to proceed to the examination of the fact, and on due proof thereof either by the voluntary confession of the party, or by the oath of one credible witness, to give judgment or sentence, and to issue warrants under their hands, for levying the same on the goods and chattels of the offender, and to cause sale to be made thereof, if not redeemed in (not less than four, nor more than eight days, 27 Geo. II. c. 20.) ; and for want of sufficient distress, to imprison the party offending till satisfaction be made. The justices, commissioners, or sub-commissioners, respectively, where they shall see cause, may mitigate, compound, or lessen, the forfeiture, penalty, or fine; so as the same be not made less than double the value of the duty of excise which ought to have been paid, besides the reasonable costs and charges of such officers, or others

as were employed therein, to be to them allowed by the said justices. (12 C. II. c. 24.) No appeal in any cause of excise shall be admitted, till the appellant hath deposited the single duty with the commissioners or sub-commissioners, and given security to the commissioners of appeal, or justices of the peace, where the cause is to be finally adjudged, for such forfeiture as was adjudged against him. (15 C. II. c. 13.) By the same statute all differences and appeals about the excise shall be heard in the proper county, and not elsewhere, and appeals within London and its limits, shall be within two months after judgment, and notice given or left at the dwelling house of the party, in all other places in four months and not otherwise.

By 43 Geo. III. c. 69, after fifth of July 1803, all duties, allowances, bounties and drawbacks of excise, and other duties under the management of the commissioners, granted by any act of parliament then in force, shall cease; except in cases relating to the recovery of arrears, or of any fine, &c. previously incurred. Provided that the act shall not extend to alter the duties upon malt, mum, cyder, and perry, granted by 43 Geo. III. c. 3. or upon malt, tobacco, and snuff, continued by 43 Geo. III. c. 4; (except as to the duties on tobacco licences, and on tobacco of Spain and Portugal); nor shall the act extend to the countervailing duties on importation from Ireland, or the drawbacks payable on exportation thither, according to the "Act of the Union;" (except those in respect of beer, ale, and wines, bricks and tiles, cyder and perry, hops, mead or metheglin, spirits, vellum and parchment, gilt and silver wire, and gold and silver thread, lace or fringe.) And in lieu thereof shall be raised and collected upon the several goods, wares, merchandize, and commodities, described in schedules annexed to the said act, and for the sales by auction, and upon licences mentioned in one of these schedules, the several sums and duties respectively set forth in the said schedules; and that there be allowed in respect of goods, &c. for which any duty of excise is imposed, the several drawbacks of excise as set forth in another schedule, and also all allowances directed to be made by any act in force on the said 1st of July 1803, except as herein altered. And by 43 Geo. III. c. 81. certain additional duties inserted in an annexed schedule are directed to be paid, and the drawbacks in another schedule shall be allowed; to commence from July 5, 1803, where no date is inserted in the act, and the amount of the additional duties may be added to the price of articles contracted for prior to the act. And the said new duties shall be raised, levied, collected, consumed, paid, recovered, adjudged, mitigated, and allowed, (except where altered by these acts or either of them) in the like manner, and by such means, ways, and methods as the former duties. And all conditions, regulations, rules, restrictions, and forfeitures; and every pain, penalty, fine, or forfeiture of any nature or kind whatsoever, for any offence against any act of parliament then in force; and the several clauses, powers, and directions therein contained, (unless altered hereby,) shall extend to and be applied in the execution of these acts, in as full and ample manner as if the same were repeated and re-enacted in the body of these acts, 43 Geo. III. c. 69. § 4. c. 81. § 3. And in all cases where duties are imposed or drawbacks allowed by these acts on any specific quantity of goods, the same shall apply after the same rate to any less quantity. 1d.

The excise duties of England are under the management of nine commissioners, who sit in the general "Excise office," having salaries of 1200*l.* a-year each, and they are obliged, by oath, to take no fee or reward, but from the king only. From these commissioners there lies an appeal to five others, called "Commissioners of Appeal." The commissioners

## EXCISE.

commissioners of excise in Scotland are five in number, and have salaries of 600*l.* per annum each.

The number of officers employed in this branch of the revenue is very great. Beside the commissioners above-mentioned, and their subordinate officers, as registers, messengers, &c. there is an auditor of the excise, and an auditor of hides, with their clerks, &c. A comptroller of cash, and another of accounts, with their clerks; a register; secretary; solicitor; receiver-general, with his clerks; clerk of securities; store-keeper; house-keeper; door-keepers; general accountants, with their assistants; accountant for fines, and two accountants for the London brewery; clerk of the bills of exchange; examiners; clerk for supervisors diaries; five general surveyors; general surveyors of distillery; and brandy; examiners of the distillery, of the brewery, and of soap and candles; surveyors of glass, of coaches, and plate licences; inspector of spirituous liquors, licences, and coaches; inspectors general of coffee, tea, &c. and of brewery through England and Wales. Beside which, there are in England and Wales, exclusive of the bills of mortality, within which is the principal head office of excise, to which all other offices in the kingdom are subordinate and accountable, about fifty collectors, who go their respective rounds once in six weeks: the province of a collector comprehends several districts, within each of which there is a supervisor, under the inspection of the collector; and each district is parcelled out into out-rides and foot-walks, within each of which there is an inferior officer, constituted under the hands and seals of the commissioners, or sub-commissioners, in their respective divisions, as necessity requires, and called gauger, or exciseman, under the inspection of the supervisor, who every six weeks draws out a diary of every day's business, with remarks, and transmits it to the chief officer. Every person, previous to his appointment to the office of gauger, must procure a certificate of his age, which must be between 21 and 30; he must understand the four first rules of arithmetic, state what business he hath followed, and that he is not encumbered with debts, be of the communion of the church of England, and, if married, not have more than two children; he must nominate two able persons to be his sureties; and the certificate, containing these particulars, and written by himself, must be signed by the supervisor of the district where he lives, and accompanied with an affidavit, that he has used no bribes for obtaining this office. He is then ordered for instruction, under the care of an experienced officer, and to wait, under the denomination of an "expectant," till a vacancy happens. Upon admission of officers of every kind relating to the excise, the oaths of allegiance and supremacy, and an oath of faithfulness in the execution of the particular office, must be taken, and the declaration against transubstantiation must be subscribed. The officers of excise are appointed, and may be dismissed, replaced, or altered by the commissioners under their hands and seals; their salaries are allowed and established by the treasury: and by 1 William and Mary, c. 24. § 15. if it be proved by two witnesses that any officer has demanded or taken any money, or other reward whatever, except of the king, such offender shall forfeit his office. Officers of excise, taking a bribe, are liable to a forfeiture of 10*l.* 15 Car. II. cap. 11: and a person liable to excise duties offering them a bribe, &c. shall forfeit 50*l.* 11 Geo. cap. 30. Officers meddling in elections are subject to a penalty of 10*l.* and an incapacity of holding any office under the king, 5 W. cap. 20. And an officer, either of the excise or customs, dealing in exciseable liquors, shall forfeit 50*l.* and be incapable of any office in the revenue, 12 Geo. cap. 28. The concealment of exciseable goods is subject to a forfeiture of those goods, and treble

value, 11 Geo. cap. 30. Any person obstructing an officer in the execution of his duty, shall forfeit 10*l.* 6 Geo. cap. 21. Actions of assault upon any officer may be tried in any county, 9 Geo. II. c. 35. And if any person shall disturb or oppose any excise officer in the execution of the powers and authorities by this act granted, or any or either of them, except where other penalties are by the act provided, he shall forfeit 200*l.* 42 Geo. III. c. 38. And the same penalty is inflicted by 43 Geo. III. c. 81, in relation to that act. Officers of excise are empowered to search at all times of the day, enter warehouses, &c. And if officers suspect that exciseable goods are concealed in any place within the limits of the chief office of excise in London, upon oath by such officers before the commissioners, or any two or more of them; or if such place be in any other part of Great Britain, on oath before one or more justices of the county, &c. or suspected place, setting forth the ground of suspicion, the said commissioners, or the said justice or justices may, by special warrant, authorise such officers by day or night (but if in the night, in presence of a constable or other peace officer) to enter into such place and to seize all such goods; and if any person shall obstruct any such officers so authorised, or any one acting in the execution of such warrant, he shall forfeit 100*l.* 42 Geo. III. c. 93. The officers, in their permits for removing exciseable goods, shall express as well the time for which they shall be in force for removing such goods, as the time within which they shall be received into stock by the person to whom they are sent; and if not removed within the time limited (unavoidable accidents excepted), or, in default of such removing, if the permit shall not be returned to the officer who granted the same, the person procuring the permit shall forfeit treble value of the goods: and if not received into stock, within the time limited, by the person to whom they were permitted to be sent, they shall be deemed goods removed without a permit. 21 Geo. III. c. 55. No writ shall be sued out against any officer of excise, or his assistant, for any thing done in the execution of his office, until one calendar month's notice shall have been delivered to him, or left at his usual place of abode, clearly and explicitly containing the cause of action, the name and place of abode of the person who is to bring such action, and the name and place of abode of his attorney or agent: and the officer may at any time within such month tender amends, and plead such tender in bar of the action; and if, upon issue joined, the jury shall find the tender to have been sufficient, they shall give a verdict for the defendant; but if the jury find that no amends, or such as were not sufficient, were tendered, they shall give a verdict for the plaintiff, and such damages as they shall think proper with costs of suit. 23 Geo. III. c. 70. If any action shall be brought against an officer, &c. it shall be brought within three months after the cause of action shall arise, and not afterwards, and shall be laid in the proper county; and if the plaintiff shall be nonsuited, or discontinued, or if upon a verdict or demurrer judgment shall be given against him, the defendant shall recover treble costs.

The additional duties, which the progress of the public expenditure has rendered it necessary to impose, have greatly increased the produce of the excise, and rendered it the most important branch of the public revenue. The duties which it comprehends are divided into the permanent consolidated duties, the temporary war taxes, and the annual duties; the latter consist of the old annual malt duty, and of an additional malt duty, which, with some duties on tobacco and snuff, and some custom duties, have, since the project for selling the land-tax, been granted annually in lieu thereof.

EXCISE.

EXCISE.

Allowances, Bounties, Pensions, Net Produce, and Payments into the Exchequer, of the Excise Consolidated Duties, 5th January 1809; distinguishing the Gross Receipt, Net Produce, and Net Payments into the Receiver-General, at the Commencement and Termination of the Year.

Overcharges, Overpayments, Repayments per Treasury, Warrant, &c.	Annual Payments to Officers of the late Wine Licence Office, and of the late Salt Duties.	Pensions	Net Produce of each Article.	Net Payments into the Exchequer.	Exchequer Payments less than Net Produce.	Resting on the 5th January 1808.	Exchequer Payments more than Net Produce.	Resting on the 5th January 1809.	Imprests.

The produce, &c. of the excise duties in Scotland for the period above stated appears from the following abstract :

	£.	s.	d.
Cash resting to be accounted for at 5th of January, 1808	38,653	1	2½
Gross receipt from 5th January, 1808, to 5th January 1809	2,086,283	19	3½
	2,124,937	0	6
Charges of management, exports, and allowances	325,768	0	10½
Disbursements out of the net produce	88,012	12	3½
Remitted to London	1,623,000	0	0
Resting to be accounted for at 5th January, 1809	83,156	7	4
	2,124,937	0	6

The total payments out of the revenue of excise, under the authority of warrants from the barons of exchequer, to the receiver-general of crown rents and casualties in Scotland, from January 5, 1808, to January 5, 1809, are as follow :

	£.	s.	d.
Salaries to the judges and officers of the three courts of session, judiciary, and exchequer, and of the admiralty and commissary courts	50,340	12	10½
Paid to those on his majesty's civil list establishment, not belonging to the three courts	22,727	10	10½
To Francis lord Napier, commissioner to the general assembly of the church of Scotland	2,000	0	0
To John Connel, procurator for the church of Scotland, to be distributed by him among itinerant preachers	1,000	0	0
To A. Mundell, without account	1,208	17	6
Total	77,277	1	3½

The total revenue of inland excise and licences, together with other fees received by revenue excise collectors in Ireland, for one year, ending the 5th of January, 1809, amounted to 1,659,838*l.* 8*s.* 9½*d.* and the total payments for management, militia, bounties, &c. out of the gross and net revenue of excise, during the same period, amounted to 531,910*l.* 9*s.* 5*d.* If we add to the above sum 1,659,838*l.* 8*s.* 9½*d.* the amount of the inland duties, viz. 429,824*l.* 11*s.* 0½*d.* the gross produce will amount to 2,089,662*l.* 19*s.* 9½*d.* and the amount of the net produce was 1,772,615*l.* 16*s.* 2½*d.*

EXCISION, in *Surgery*, is a word often used to signify the operation of cutting any tumour, or any foreign substance, off, or out of, a part of the body.

EXCITABILITY, in Dr. John Brown's hypothesis, or the *Brunonian* hypothesis; as it has been called, is nearly synonymous with the *vital principle* of medical writers in general, and signifies that quality or property of living beings, on which the phenomena of life depend.

Life itself is, in the opinion of Brown, a *forced state*, arising altogether from the action of certain agents, which he denominates *exciting powers*, upon the *excitability*; for death ensues equally, whether the exciting powers are withdrawn, or the excitability is lost. The exciting powers

consist of heat, air, food, drink, and other substances taken into the stomach, the blood, and the fluids secreted from it; as well as of certain functions of the system itself, such as muscular exertion, sensation, thought, and passion or emotion. The effect of the exciting powers acting upon the excitability, is denominated *excitement*.

This word "excitability" is to be considered as a general term, expressive of the facts ascertained by observation, but of the essential nature of which we must remain ignorant; as in the case of gravitation, &c. "We know not what excitability is," says Dr. Brown, "or in what manner it is affected by the exciting powers. But whatever it be, whether a quality or a substance, a certain portion is assigned to every being upon the commencement of its living state." He observes, however, that such expressions as a determinate portion of excitability in each living being, the exhaustion, or the accumulation of excitability, are necessarily borrowed from the qualities of material substances, in consequence of the poverty of language; and are not to be received in a strict and literal sense.

Every power, then, that acts on the living frame, according to this doctrine, is stimulant, or produces excitement by expending excitability; whence "it follows, that the whole phenomena of life, every state and degree of health and disease, are also owing to stimulus, and no other cause." By too great stimulation weakness is induced, because the excitability becomes defective; this is said to constitute a state of *indirect debility*; when the exciting powers or stimulants are withheld or diminished, weakness is likewise induced, the excitability being accumulated, or in excess; and this is denominated a state of *direct debility*. (See DEBILITY.) For "this mutual relation obtains betwixt excitability and excitement; that the more weakly the powers have acted, or the less the stimulus has been, the more abundant the excitability becomes;—the more powerful the stimulus, the excitability becomes the more exhausted." It is only then, when a mean degree of stimulus operates upon excitability at a medium, that perfect health is produced: in illustration of which a scale was drawn by Brown, (See Elements of Medicine, chap. iii. § 39. note) divided into 80 degrees of excitability opposed inversely to 80 degrees of exciting power, at each end of which is *death*; there being, in the one case, 80 degrees of excitability, and no exciting power; and in the other, 80 degrees of stimulus and no excitability; whereas *perfect health* holds the middle station, where there are 40 degrees of stimulus and of excitability respectively. Good health, however, may be considered to exist within a range of 30 or 40 degrees (15 or 20 on each side of the mean) in consequence of the constant variation of stimulus, to which man is exposed, in his food, drink, passions of the mind, &c.; but every departure from the mean of perfect health constitutes a pre-disposition to diseases of direct or indirect debility. As life is entirely regulated by excitement, and the exciting powers have a stimulating effect only, Dr. Brown affirms, that "the notion of health and disease being different states is disproved;" the operation of the powers producing or removing each state being perfectly identical: and efficacious remedies being such as oppose deficient stimulus to excessive excitement, and excessive stimulus to deficient excitement. In a word, there are but *two* forms of diseases; and both are always preceded by pre-disposition; those which arise from excessive excitement are called *sthenic* (from σθενος, strength,) and those which originate from a deficient excitement, *asthenic*. The direct tendency of this hypothesis, therefore, was to reduce the art of medicine to the simple regulation of stimuli, or of the exciting powers; it required

## EXCITABILITY.

us only to increase the quantity of stimulation on the one hand, or to withdraw, or rather diminish, the stimuli on the other, as the excitement happened to be too great or too little, above or below the medium of the scale of health.

As this concise statement of a medical hypothesis, which has excited great attention and much controvery, may, perhaps, be obscure to those who are unaccustomed to the study of the phenomena of animal life, we shall cite an illustration of Brown's system, drawn up by one of his pupils from a familiar operation, by which a conception of his fundamental principles may be facilitated.

"Suppose a fire to be made in a grate filled with a kind of fuel not very combustible, and which could only be kept burning by means of a machine, containing several tubes, placed before it, and constantly pouring streams of air into it. Suppose also a pipe to be fixed in the back of the chimney, through which a constant supply of fresh fuel was gradually let down into the grate, to repair the waste occasioned by the flame, kept up by the air-machine.

The grate will represent the human frame; the *fuel* in it the *matter of life* (the *excitability* of Brown, and the *sensorial power* of Darwin): the tube behind, supplying fresh fuel, will denote the power of all living systems constantly to regenerate or reproduce excitability; while the air-machine, of several tubes, denotes the various *stimuli*, or exciting powers, applied to the excitability of the body; and the flame, drawn forth in consequence of that application, represents *life*, the product of the exciting powers acting upon excitability.

As Dr. Brown has defined *life* to be "a forced state," it is fitly represented by a flame, *forcibly* drawn forth, from fuel little disposed to combustion, by the constant application of streams of air poured into it from the different tubes of a machine. If some of these tubes are supposed to convey pure, or *oxygenous* air, they will denote the highest class of exciting powers, such as opium, musk, camphor, spirits, wine, &c. (the diffusible stimuli of Dr. Brown) which bring forth for a time a greater quantity of life than usual, as the blowing in of pure air into a fire will temporarily draw forth an uncommon quantity of flame. If others of the tubes be supposed to convey common or atmospheric air, they will represent the ordinary exciting powers, or stimuli, applied to the human frame, such as heat, light, air, food, drink, &c.; while such as convey impure airs may be used to denote what have formerly been termed sedative powers, such as poisons, contagious miasmata, foul air, &c. (Sedatives are deemed by Brown stimulants of a minor force.)

The reader will now be at no loss to understand the seeming paradox of the Brunonian system, that food, drink, and all the exciting powers applied to the body, though they *support* life, yet they *consume* it; for he will see, that the application of these powers, though it brings forth *life*, yet at the same time it wastes the excitability, or *matter of life*; just as air blown into the fire brings forth more *flame*, but wastes the *fuel*, or *matter of fire*. This is conformable to the common saying, "the more a spark is blown, the brighter it burns, and the sooner it is spent." A Roman poet has given us an excellent illustration of the Brunonian system, when he says,

"Balneæ, vina, Venus, consumunt corpora nostra;  
Sed vitam faciunt balneæ, vina, Venus."

"Wine, warmth, and love our vigour drain;  
Yet wine, warmth, love our life sustain."

It will be equally easy to illustrate the two kinds of *debility*, termed *direct* and *indirect*, which, according to Brown, are the causes of all diseases; if the quantity of stimulus, or excit-

ing power, is proportioned to the quantity of excitability; that is, if no more excitement is drawn forth, than is equal to the quantity of excitability produced, the human frame will be in a state of health; just as the fire will be in a vigorous state, when no more air is blown in, than is sufficient to consume the fresh supply of fuel, constantly poured down by the tube behind. If a sufficient quantity of stimulus is not applied, or air not blown in, the excitability in the man, and the fuel in the fire, will accumulate, producing *direct debility*; for the man will become *weak*, and the fire *low*. This, carried to a certain degree, will occasion death to the fire, and extinction to the last. If again, an over proportion of stimulus be applied, or too much air blown in, the excitability will soon be wasted, and the matter of fuel almost spent: hence will arise *indirect debility*, producing the same weakness in man, and lowness in the fire as before, and equally terminating, when carried to a certain degree, in death and extinction."

The simplicity of this doctrine, contrasted with the complicated hypotheses of preceding physicians, and its happy illustration of some of the phenomena of life, (which we have noticed under the word *DEBILITY*;) speedily obtained for it a number of profelytes, in the schools of medicine, wherever it was introduced. A generalization so sweeping was, indeed, well calculated to arrest the attention, and gratify the ardour of young minds; and accordingly it was espoused with enthusiasm by the most sanguine and speculative students, and was debated and defended with a vehemence and intolerance of opposition, almost unknown in scientific discussions; and this not only at Edinburgh, where the doctrine originated, but successively in the different universities of the continent to which it was carried. To learn that there were but two forms of disease, and therefore but two indications of cure, and two sets of remedies, was particularly gratifying to those who preferred indolent hypothesis to the labour of observation. It superseded at once the practice and maxims of the Hippocratic school of experience and unremitting investigation, and reduced the art of medicine within the compass of a nut-shell.

But, true as this doctrine of excitement may be, in its application to many of the phenomena of life, it is by no means adequate to the explanation of the whole, and especially of the causes and remedies of numerous diseases: it is, moreover, inconsistent with itself in some points, and its advocates are not agreed in the interpretation of these difficulties.

There is one inconsistency so gross and obvious, in the Brunonian doctrine, that it is inconceivable how the author could have been insensible of it, or have persevered in maintaining it. In the illustration above quoted, a tube or chimney is provided, by which the fuel, or excitability, is supposed to be constantly replenished: but no such provision is mentioned by Brown. He affirms that "a certain portion of excitability is assigned to every being at the commencement of its existence, that the action of stimuli necessarily exhausts it, and that life consists in the incessant action of stimuli upon this excitability;" *i. e.* in the incessant exhaustion of it. With this statement the notion of accumulated excitability (which is said to constitute *direct debility*) is altogether incompatible: non-consumption, or rather diminished consumption, might preserve the excitability, but surely could never increase it: though somewhat might be saved, nothing could be gained, by the abstraction of stimuli; and on the re-application of the discontinued stimuli, the excitability should never be found increased or accumulated, but should be stationary at the point of interruption; or, more correctly speaking, it must always be found

found somewhat wasted, since, while life remains, it must be acted upon in some degree; while, on the other hand, every violent stimulation should, upon the same principle, rapidly waste, and hasten the irrecoverable exhaustion of the powers of life. The proposition, then, that a determinate portion of excitability is assigned to every individual, being equally inconsistent with the subsequent theorems of the system, and with matter of fact, has been either given up, or explained away, by the pseudo-Brunonians of the present day. They admit that the excitability may be partially restored or renewed by rest and food. But to make the hypothesis consistent with common sense, it requires that the process of *generating* excitability be constantly going; for even during the most profound sleep, stimuli, or, in other words, exhausting powers, are incessantly applied, the cessation of all excitement being synonymous with death.

Another inconsistency in the hypothesis, scarcely less palpable, is the statement, that *indirect* debility, which consists in exhaustion of the excitability from excessive stimulation, is to be cured, *i. e.* the excitability is to be restored, by a continuance of strong stimuli; namely, by stimuli "*little short* of those which produced the over-excitement." But, however managed, it is obvious from the hypothesis, that they must exhaust excitability, if they act at all; they must, therefore, wear out what remains of the excitability more and more, and ultimately exhaust the power. No attempts to explain away this incongruity of language can be considered successful; the alleged loss of power in the stimuli, in consequence of repetition, will only account for the less rapidity of the complete exhaustion; but exhaustion of excitability cannot be separated from the notion of stimulation.

In its application to the practice of medicine, as well as to the explanation of the action of many causes of disease, the Brunonian system is marked by a gross neglect or defiance of observation and experience. The connections and dependencies of the different functions, the local derangements which take place in the different organs, and the curative indications deduced from these, are altogether overlooked; and the variety of phenomena which result from the specific operation of various agents on the animal economy, is equally neglected. The assertion that all powers, which influence the animal body, whether productive or curative of disease, are *stimulants*, is an abuse of language not often equalled by the framers of theories. There is not only not an identity in their action;—there is scarcely any thing in common. "With regard to contagions," to use the words of an intelligent critic, "when we consider the regular and progressive series of actions, induced by these on the system; when we have observed that each contagion gives rise to a train of peculiar and characteristic phenomena, defining the disease whence the contagion originated, and terminating often in the formation and separation of a quantity of morbid matter, alone capable of propagating the same disease in others, we cannot acknowledge that identity in the operation of the exciting powers, which the Brunonians contend for. In diseases induced by contagions, in the small-pox, for example, or in lues venerea, we perceive something more than simple excitement and unvaried stimulation. Individuals of every description, whether predisposed to *sthenia* or *asthenia*, whether labouring under direct or indirect debility, may be infected; and when the disease has taken place, it runs its course under every possible modification of the excitability, &c." (See Edinburgh Med. and Surg. Journal, vol. i. p. 369.) And again, with respect to the agents of the *Materia Medica*, besides their action upon the excitability, or the degree of excitement and ex-

haustion which they produce, there are various other peculiarities in their mode of operation. "They differ in the succession of phenomena to which they give occasion; the intoxication produced by wine, opium, and some other narcotics, cannot be imitated by aromatics, by the preparations of antimony or of mercury; nor the effects of these by narcotics: they differ in their power of specifically affecting particular organs and functions, as the stomach, intestines, kidneys, skin, salivary glands, absorbent or vascular system; by emetics, purgatives, diuretics, sudorifics, mercury, digitalis, &c. They differ in their power of opposing and inducing particular organic changes and morbid affections of the system; as syphilis and biliary diseases are cured by mercurials, scurvy by vegetable acids, and uric diseases by alkalis: they differ in the durability of effect or change produced; as is obvious by comparing the momentary and fleeting effects of the diffusible stimuli, with the permanent excitement and vigour produced by tonics, as by cinchona and preparations of iron, by wholesome food and pure air." *Loc. cit.*

In short, it is obvious that the word *stimulant*, as applied to all these various actions upon the living system, no longer retains any definite meaning; but produces a jargon which may be interpreted by each individual according to his own notions. In this respect, the theory possesses an universal fitness, like Bayes' prologue, and will do for any practice that may be found most expedient. Thus mercury will be considered as the proper *stimulant* for syphilis, cinchona and arsenic for intermittents, citric acid for scurvy, and so on; for fortunately mankind have still good sense enough to accommodate their hypotheses to the results of experience: hence we do not apprehend, that many of the most implicit believers in this jargon would endanger their patients by applying the same remedies to typhus, gout, and dropsy, because they stand in the same numerical portion of the scale; or by treating phthisis, apoplexy, and the plague alike, because they are classed together in the same way!

Notwithstanding its many inconsistencies and defects, however, the Brunonian doctrine has had some beneficial influence on medical science, by inducing a particular attention to the degree of excitement, which accompanies many diseases, although it cannot be considered as the cause or essence of them. The regulation of the excitement often constitutes the most useful means of conducting these diseases through their course to a safe termination, by moderating symptoms, and keeping action within due bounds on the one hand, or supporting the languid forces of the system on the other. This is especially true with regard to contagious febrile diseases.

The doctrines of Brown are contained in the "*Elementa Medicinæ*," which were first published in Latin, and afterwards translated by himself. After his death a revised edition of this translation was published by Dr. Beddoes, in 2 vols. 8vo. 1795; and another by the author's son, Dr. William Cullen Brown, in 3 vols. 8vo. in 1804. See BROWN.

EXCITATION, (from the Latin *excito*, I excite,) denotes the act of awakening, of rousing, or of producing some power or action; thus we hear of the excitation of motion, excitation of heat, excitation of passions, &c. In natural philosophy this word is principally used in the subjects of electricity and of heat; and of these two kinds of excitation the particulars are as follows.

When a piece of amber, or of glass, or of sulphur, or in short, of any other solid, called *electric*, or *non-conductor*, is observed in common, it does not appear to have any particular power; but if it be rubbed with a dry hand, or with something else, then after a few strokes it will be found

## E X C I T A T I O N .

that it has acquired the electric virtue, so that now it will attract small bodies that are presented to it, and it will also exhibit other electrical phenomena (for which see the article *ELECTRICITY*.) In this case the electric power in the amber, or glass, or sulphur, is said to have been *excited* by the friction of the hand or other body, which therefore is called the *rubber*; for, previous to the friction, the amber, or sulphur, &c. shewed no signs of electricity, that power being, as it were, dormant in it.

Rubbing is the most general, and upon the whole, the most effectual method of exciting electrics, but there are several other modes of excitation, and indeed hardly any action, or any motion, takes place among natural bodies, which is not attended with the excitation of electricity. In general, however, the electricity is not produced in quantity sufficient to affect our senses, without the aid of proper instruments, and of course it passes unnoticed. The principal causes of the excitation of electricity are rubbing or friction, heating and cooling, melting or coagulating, evaporation and condensation, expansion and contraction, the mere juxtaposition or contact of certain bodies, solution and effervescence, and lastly some unknown action of the body in certain aquatic animals. But these methods are not indiscriminately applicable to all substances. They are confined within certain limits of application as well as of effect; and of these particulars we shall now give a regular account.

*Rubbing, or friction.*—In the science of electricity the various bodies of the earth are distinguished into electric and conductors (see *ELECTRICS* and *CONDUCTORS*;) and whenever two bodies are rubbed against each other, unless they be both very good conductors, some electricity is always produced; that is, one of the bodies acquires the positive or vitreous, and the other acquires the negative or resinous electricity; for by this means one kind of electricity cannot be produced without the other. The circumstance which, in the superficial manner of performing the experiment, makes it appear as if one kind only of electricity were produced, is that the best conductor of the two bodies concerned, being not insulated, loses its electricity as soon as it receives it; but when both bodies are insulated, each of them will become electrified by the friction, one of them acquiring the positive, and the other the negative electricity. Even two insulated perfect conductors, by the least contact or friction against each other, acquire a slight degree of electricity; but of this hereafter. The friction which is required for this excitation of electricity is not that which can scrape off or injure the surface, but a gentle pressure progressively applied with a pretty quick motion. The former hard kind of friction generates heat, but little or no electricity.

The very same body, by changing the rubber, may be caused to acquire either the positive or the negative kind of electricity; and the change is often produced by a remarkably slight alteration of circumstances, such as altering the direction of the friction, increasing or diminishing the temperature by a few degrees, and so forth. The following table exhibits the principal cases of this kind of change, *viz.* it shews what kind of rubber is required for exciting a given body positively, and what kind for exciting it negatively. Thus it appears that sealing-wax acquires the positive electricity when rubbed with a metallic body, and that it acquires the negative electricity when rubbed with furs, leather, woollen cloth, &c. Thus also it shews that baked wood is excited positively by silk, and negatively by flannel.

<i>Substance rubbed.</i>	<i>Electricity.</i>	<i>Rubber.</i>
The fur on the back of a cat.	Positive	Every substance with which it has hitherto been rubbed.
Smooth glass.	Positive	Every substance hitherto tried, excepting The fur on the back of a cat.
	Negative	
Rough glass.	Positive	Dry oiled silk, sulphur, metals. Woollen cloth, quills, wood, paper, sealing-wax, white-wax, the human hand.
	Negative	
Tourmalin.	Positive	Amber, air, <i>viz.</i> by blowing with the bellows upon it. Diamond, the human hand.
	Negative	
Hare's skin.	Positive	Metals, silk, loadstone, leather, hand, paper, baked wood. Other finer furs.
	Negative	
White silk.	Positive	Black silk, metals, black cloth. Paper, hand, hairs, weasel's skin.
	Negative	
Black silk.	Positive	Sealing-wax. Hare's, weasel's, and ferret's skin, the load stone, brass, silver, iron, the human hand.
	Negative	
Sealing-wax.	Positive	Metals. Hare's, weasel's, and ferret's skin, the hand, leather, woollen cloth, paper.
	Negative	
Baked wood.	Positive	Silk. Flannel.
	Negative	

When two electric substances, equal in every respect, are rubbed against each other, that substance which suffers the greater degree of friction acquires the *negative*, and the other acquires the *positive* electricity. Thus, if a piece of silk, A, be drawn across another piece of silk, B, in every respect equal to A, so that the surface of the whole piece, A, (*viz.* of one side of it,) be successively drawn over one part of the piece B, then A will acquire the *positive*, and B the *negative* electricity. The reason of this probably is the greater degree of heat which the rubbed part of B acquires by the friction, it having been observed by Bergman, that heat rather disposes bodies to acquire the negative electricity.

Glass, when warmed a little, as about the temperature of 110° of Fahrenheit's scale, may be excited more easily and more powerfully than at a lower temperature. A great part of this effect probably depends upon the glass being less apt to attract moisture in that elevated temperature.

Mr. Henly insulated several bodies, and in that state rubbed them, one by one, against his woollen garments, or against silk, by which means they became electrified; but he observed very great irregularities in the effects which

## EXCITATION.

were produced by substances much allied to each other, or of the same class. Thus, a guinea, a six-pence, and a piece of tin, became negative; a piece of copper, a steel button, and a silver button, positive, at least when the cloth was warm; animal substances, excepting shells, generally acquired the positive electricity; vegetables became almost always negative; but the smooth skins of bears became positive; common pebbles, marble, coal, and jet, acquired the negative electricity; gems and crystals, the positive; glazed wares and writing paper, the positive; tobacco pipe, elastic gum, a tallow candle, oiled silk, Indian ink, and blue vitriol, (*viz.* sulphate of copper,) acquired the negative electricity. Other persons have extended the list considerably farther, but it is useless to specify the particulars.

The principal requisite in the subject of electricity, is to determine the proper construction of the rubber, and the method of employing it, so as to excite the greatest possible power in a given electric.

The best rubber for a tube of smooth glass, Mr. Cavalla says, (*Treatise on Electr.*) is the rough side of black oiled silk, especially when a little amalgam has been rubbed upon it; but the best rubber for a rough glass tube, a stick of baked wood, sealing-wax, or sulphur, is soft new flannel. The rubbers of common electrical machines, wherein a glass globe, or cylinder, or circular plate is revolved, has been varied and improved progressively. The more common construction consists of nothing more than a silk cushion stuffed with hair, over which is placed a piece of leather, and upon this leather some amalgam, (*see AMALGAM for electrical purposes,*) is spread so as to adhere pretty fast to it. Some time ago it was customary, (and the practice even at present is not entirely laid aside,) to make the rubber of red basil skin stuffed with hair; but the above-mentioned silk one, which was contrived by Dr. Nouth, is much preferable. If this silk cushion, on account of adapting it to the surface of the glass, is to be fixed upon a metallic plate, then care should be taken to render the plate free from sharp points, edges or corners, and it should be concealed or covered over with the silk. In short, to construct the rubber properly, it must be made so, that the side of it which the surface of the glass enters in whirling, may be as perfect a conductor as can be made, in order to furnish an ample and ready supply of electricity, and the opposite part should be as much a non-conductor as possible, in order that none of the electricity that has been accumulated upon the glass may go back to the rubber. A piece of silk is generally fixed to the extremity of the leather which stands against the surface of the glass. The rubber of Mr. Nairne's electrical machine (*see ELECTRICAL Machine,*) consists of silk only put over the leather cushion, the piece of silk projecting a considerable way beyond the cushion, and very little amalgam is used with it: in truth no amalgam at all is put upon the rubber of this machine; but whilst the clean rubber is on, and the cylinder is turning, a piece of leather, with some amalgam spread upon it, is applied for a few seconds to the under part of the cylinder, by which means a sufficient number of particles of amalgam will fly along the surface of the glass, from the leather to the rubber.

The rubber should be supported by a spring, by which means it may easily adapt itself to the inequalities of the surface of the glass, which, with cylinders, often are very considerable. It should likewise be insulated in whatever manner it may be most convenient; for whenever insulation is not wanted, a chain or wire may be occasionally

hung upon it, by which means it will communicate with the ground or with any other body at pleasure: when there is no possibility of insulating the rubber, several of the most interesting experiments in electricity cannot be performed with the machine.

Mr. Nicholson made a great variety of experiments, respecting this mode of excitation, which are described at large in the *Philosophical Transactions* for the year 1789, and from those experiments he deduces the following inferences.

"Those experiments," he says, "shew that the office of the silk is not merely to prevent the return of electricity from the cylinder to the cushion, but that it is the chief agent in the excitation, while the cushion serves only to supply the electricity, and perhaps increase the pressure at the entering part. There likewise seems to be little reason to doubt but that the disposition of the electricity to escape from the surface of the cylinder, is not prevented by the interposition of the silk, but by a compensation after the manner of a charge, the silk being then as strongly negative as the cylinder is positive; and, lastly, that the line of light between the silk and the cushion in weak excitations, does not consist of returning electricity, but of electricity which passes to the cylinder, in consequence of its not having been sufficiently supplied, during its contact with the rubbing surface.

"When the excitation was very strong in a cylinder newly mounted, flashes of light were seen to fly across its inside, from the receiving surface to the surface in contact with the cushion, as indicated by the brush figure. These made the cylinder ring as if struck with a bundle of small twigs: they seem to have arisen from part of the electricity of the cylinder taking the form of a charge. This appearance was observed in a nine-inch, and a twelve-inch cylinder, and the property went off in a few weeks. Whence it appears to have been chiefly occasioned by the rarity of the internal air produced by handling, and probably restored by gradual leaking of the cement."

In order to determine what takes place in the inside of the cylinder, Mr. Nicholson undertook a series of experiments with a plate machine, (*see ELECTRICAL Machine,*) and from their result it appears, "that no advantage is gained by rubbing both surfaces, but that a well-managed friction on one surface will accumulate as much electricity as the present methods of excitation seem capable of collecting; but that when the excitation is weak, on account of the electric matter not passing with sufficient facility to the rubbed surface, the friction enables the opposite surface to attract or receive it, and if it be supplied, both surfaces will pass off in the positive state, and either surface will give out more electricity than is really induced upon it, because the electricity of the opposite surface forms a charge. It may be necessary to observe, that I am speaking of the facts or effects produced by friction; but how the rubbing surfaces act upon each other to produce them, whether by attraction or otherwise, I do not here enquire."

From farther experiments with the cylinder, Mr. Nicholson deduced the following conclusions: "the line, he says, of light on a cylinder departing from a simple cushion, consists of returning electricity. 2. The projecting part of the cushion compensates the electricity upon the cylinder, and by diminishing its intensity prevents its striking back in such large quantities as it would otherwise do. 3. That if there were no such compensation, very little of the excited electricity would be carried off; and, 4. That the compen-

## EXCITATION.

compensation is diminished, or the intensity increased, in an higher ratio than that of the distance of the compensating substance; because if it were not, the electricity which has been carried off from an indefinitely small distance, would never fly back from a greater distance, and from the edge of light.

“ I hope the considerable intensity I shall speak of will be an apology for describing the manner in which I produce it. I wish the theory of this very obscure process were better known; but no conjecture of mine is worth mentioning. The method is as follows:

“ Clean the cylinder and wipe the silk.

“ Grease the cylinder by turning it against a greased leather till it is uniformly obscured. I use the tallow of a candle.

“ Turn the cylinder till the silk flap has wiped off so much of the grease as to render it semi-transparent.

“ Put some amalgam on a piece of leather, and spread it well, so that it may be uniformly bright. Apply this against the turning cylinder. The friction will immediately increase, and the leather must not be removed until it ceases to become greater.

“ Remove the leather, and the action of the machine will be very strong.

“ My rubber consists of the silk flap pasted to a leather, and the cushion is pressed against the silk by a slender spiral spring in the middle of its back. The cushion is loosely retained in a groove, and rests against the spring only in such a manner, that by a sort of libration upon it as a fulcrum, it adapts itself to all the irregularities of the cylinder, and never fails to touch in its whole length. There is no adjustment to vary the pressure, because the pressure cannot be too small when the excitation is properly made. Indeed, the actual withdrawing of the cushion to the distance of one-tenth of an inch from the silk, will not materially affect a good excitation.

“ The amalgam is that of Dr. Higgins, composed of zinc and mercury. If a little mercury be added to melted zinc, it renders it easily pulverable, and more mercury may be added to the powder to make a very soft amalgam. It is apt to crystallize by repose, which seems in some measure to be prevented by triturating it with a small proportion of grease: and it is always of advantage to triturate it before using.”

The following curious fact may, perhaps, be referred to the action of friction.—If a stick of sealing-wax be broken into two pieces, the fractured parts, that is, those extremities of the pieces which were contiguous to each other, will be found electrified, one of them positively, and the other negatively.

*Heating and cooling.*—The property of exhibiting electrical phenomena by means of heating and cooling, was first observed in a hard semi-pellucid fossil, known under the name of tourmalin (called *aschentricker* by the Dutch, from its property of attracting ashes, &c. when laid near the fire. Linnæus, in his *Flora Zeylonica*, calls it *lapis electricus*.) This stone, which generally is of a deep red or purple colour, and seldom exceeds the size of a small walnut, is common in several parts of the East Indies, and especially in the island of Ceylon. Tourmalins are also found in a great many other parts of the world, and often in pretty large masses, but they are mostly opaque, and then they hardly ever shew any peculiar electric properties. (See its mineralogical characters under the article TOURMALIN.) The tourmalin's properties with respect to electricity are as follows.

1. The tourmalin, while kept in the same degree of heat,

shews no signs of electricity; but it will become electrical by increasing or diminishing its heat, and stronger in the latter than in the former circumstance. An exceedingly small variation of temperature is often sufficient to render it sensibly electrical.

2. The electricity of the tourmalin does not appear all over its surface, but only on two opposite sides, which may be called its *poles*, and they are always in one right line with the centre of the stone, and in the direction of its strata; in which direction the stone is absolutely opaque, though on the other semi-transparent.

3. Whilst the tourmalin is heating, one of its sides (distinguished by A) is electrified plus, or positively, and the other side B, minus; but when it is cooling A is minus, and B is plus.

4. If it be heated and suffered to cool without either of its sides being touched, then A will appear positive, and B negative, all the time of its heating or cooling.

5. If this stone be excited by friction, like any other electric, then each of its sides, or both at once, may be made positive.

6. If the tourmalin be heated or cooled upon some other insulated body, that body will be found electrified as well as the stone; and will be found possessed of the electricity contrary to that which is acquired by that side of the stone which was laid upon it.

7. The electricity of each side, or of both, may be reversed by heating or cooling the tourmalin in contact with various substances; thus if it be cooled, or heated, in contact with the palm of the hand, that side of it, which would have been positive if cooled in the open air, is now negative; and that which would have been negative is now positive.

8. If a tourmalin be cut into several parts, each piece will have its positive and negative poles, corresponding to the positive and negative sides of the stone from which it was cut.

9. These properties of the tourmalin are also observable in vacuo, but not so strongly as in the open air.

10. If this stone be covered all over with some electric substance, as sealing-wax, oil, &c. it will in general shew the same appearances with this coating as without it.

11. Mr. W. Canton observed a very vivid light upon the tourmalin while heating in the dark; and this is sufficient to point out which end of the stone is become positive, and which negative. Also, when the stone is strongly excited, it emits very strong flashes from the positive to the negative end, in the dark. That stone which is commonly called the “Brazilian emerald” from its colour, but which in fact is a tourmalin, also emits the abovementioned electrical light.

12. Lastly, it is to be remarked that the power of the tourmalin is sometimes injured by the action of a strong fire, at other times it is improved, and frequently it is not at all affected by it. The laws, however, of such uncertain effects, have not yet been investigated.

Most of the above-mentioned properties, which were first observed in the tourmalin, have been found to belong to some other bodies; *i. e.* there are some other substances which have the electric virtue excited in them by heating and cooling. It is to be observed that such bodies are generally, if not always, in a crystallized state; also it has been remarked that the parts which exhibit the different states of electricity differ from each other with respect to their form, although they are similarly situated: while in those crystals that are not electric, the similarly situated parts correspond also in form. If a crystal, for instance, consist of a prism terminated at each extremity by a pyramid,

## EXCITATION.

mid, and these pyramids differ as to the kind of electricity they are capable of acquiring, it will be found that they also differ in their form; one consisting of a greater number of surfaces than the other; and the part which has the greater number of faces acquires the positive electricity; the other the negative. Kidd's Outlines of Miner. vol. i.

The Abbé Haüy says, that the electricity which is produced by heat has been observed in six species of minerals, *viz.* the tourmalin, the borated magnesia or boracite, the topaz, whether from Brazil, from Saxony, or from Siberia, the mesotype of Haüy, or zeolite, the prehnite, and the oxydated zinc, or electrical calamine. See the nature of these minerals under the articles of their peculiar names. We are informed, however, that lately a gentleman, highly versed in electrical experiments, examined a vast number of specimens of the above-mentioned six minerals, and among them, (independent of the tourmalin,) he found two only that became electrical by heating and cooling; namely, the boracite and the oxydated zinc; with respect to a specimen of the latter, which had a pyramid at one end, and was truncated at the other end, he particularly observed that whilst cooling, the pyramid became negative, and the truncated side positive; but whilst heating, the pyramid became positive, though slightly so, and the truncated side did not manifest any sensible degree of electricity.

*Melting or coagulating.*—Melting or pouring a melted electric substance into another, excites electricity in various instances, and with peculiar phenomena.

If sulphur be melted in an earthen vessel, and be left to cool upon conductors; then if taken out of the vessel, when cold, it will be found strongly electrical; but not at all so, if it be left to cool upon electrics.

If sulphur be melted in glass vessels, and afterwards left to cool, they will both acquire a strong electricity, the sulphur negative, and the glass positive, whether they be left to cool upon electrics or upon conductors; however, they always acquire a stronger power in the former case than in the latter; and a stronger still, if the glass vessel is coated with metal. It is to be remarked, that the sulphur acquires no electricity till it begins to cool; its power increases in proportion as it contracts, and is the strongest when in the state of greatest contraction; but then the electricity of the glass vessel is at the same time the weakest.

If melted sulphur be poured into a vessel of baked wood, it acquires the negative electricity, and the wood the positive; but if it be poured into sulphur, or rough glass, it does not acquire any sensible degree of electricity.

Melted sulphur poured into a metal cup, and there left to cool, shews no signs of electricity whilst remaining in the cup; but if separated, they will then appear strongly electrified, the sulphur positively, and the cup negatively. If the sulphur is replaced in the cup, every sign of electricity will vanish, but, if whilst they are separate the electricity of either of them is taken off, then, on being replaced, they will both appear possessed of that kind of electricity which had not been taken off.

Melted wax, poured into glass or wood, acquires the negative electricity, and leaves the glass or wood positive. But sealing-wax poured into sulphur acquires the positive electricity, and leaves the sulphur negative. The wax-chandlers, in making their candles, often find it extremely difficult to prevent the attraction and adhesion of dust and other light bodies, in consequence of the electrified state of the wax.

Chocolate fresh from the mill, as it cools in the pans in which it is received, becomes strongly electrical. When turned out of the pans, it retains for some time this property, but

soon loses it by handling. Mr. Henly, who made these observations upon chocolate, found that by melting it again in an iron ladle, and pouring it into the tin pans as at first, would for once or twice more renew its power; but when the mass became very dry and powdery in the ladle, the electricity could no longer be revived by simple melting. However, he found that if in that state a little olive oil be added and mixed well with the chocolate in the ladle, then on pouring it into the tin pan as at first, the electric power will be found to be completely recovered.

*Evaporation and condensation.*—It was Mr. Volta who first discovered that the evaporation of water, and of most other bodies either solid or fluid that can be converted into smoke or vapour produced electricity, and not long after it was discovered that the condensation of vapour also produced electricity, but of the contrary kind. Thus when water is evaporated from an insulated vessel, that vessel remains electrified negatively, and if the vapour be received and condensed upon an insulated surface, that surface will acquire the positive electricity. These discoveries, besides their affording an easy explanation of the origin of the electricity in the clouds, fogs, &c. seem to point out a general law of nature; namely, that the capacity of water or other fluids for holding the electric fluid, is increased by the expansion of those bodies into the form of vapour; and is diminished by the contrary operation, *viz.* by the contraction of the vapour into the form of water. Therefore, in the first case, by imbibing an additional quantity of electric fluid the vapour would leave the bodies from which it departed in a negative state; and in the second case, *viz.* in the conversion of vapour into water by giving out a quantity of electric fluid, would leave the bodies that touched it in a positive state. And this is analogous to what takes place with respect to caloric and vapour.

The easiest way of shewing the production of negative electricity by evaporation is, to place a metallic cup upon a delicate electrometer, and to put a red-hot coal in it; then on pouring a few drops of water upon the coal, a sudden evaporation takes place, and the electrometer opens with negative electricity. In order to shew the positive electricity which is produced by the condensation of vapour, let a pretty long wire (*viz.* about a foot long) proceed from the top of the electrometer, and fix some pieces of paper to the farther end of the wire, then if the steam of water which issues out of the spout of a boiling kettle be directed towards the paper, the steam will be condensed upon it, and the electrometer will open with positive electricity.

The production of electricity by evaporation is not, however, always proportional to the quantity of evaporation; for instance, when water is evaporated from certain substances it produces a considerable quantity of negative electricity, but when evaporated from certain other substances, it produces little of it or none at all. Thus the flaking of quicklime produces a copious evaporation, but no electricity; and such is likewise the case with a few other substances.

All the experiments that were made, during some years subsequent to the original discovery, shewed, that if evaporation produced any electricity at all, this was of the negative kind; but at last two remarkable exceptions from this general rule were discovered, *viz.* one by a learned professor of the academy of Mantua, and the other by Mr. Cavallo; and these exceptions seem to point out a more intimate connection between the electric fluid and other bodies.

The first of the above-mentioned gentlemen found that when water is evaporated by being poured over a red-hot piece of very rusty iron, it would leave the iron and vessel upon

## EXCITATION.

which it stood electrified positively; and the same would be the case if the red-hot piece of rusty iron was thrown into the water: supposing that the latter is contained in an insulated vessel. If the iron be clean and free from rust, the electricity will be negative; if very rusty, the electricity will be positive, and if partially rusty, it will acquire little or no electricity; for in this last case the negative electricity which arises from the evaporation of water from over the clean part of the iron, is balanced by the positive electricity, which is produced by the evaporation from over the rusty part. In consequence of this, a rusty piece of iron will not serve for more than one or two experiments, for, by rendering it red-hot, part of the rust is shaken off, and at last it will act like a piece of clean iron. *Gardenii Dissert. de Electrici Ignis Natura.* § 84, 85, 86.

The other exception (which was discovered by Mr. Cavallo, and is published in the 4th edit. of his *Treat. on El.*) is shewn by means of red-hot glass. "The various degrees," Mr. C. says, "of electric powers that are produced by the evaporation of water from different substances induced me to diversify the experiments as much as I could, in order to discover, if possible, the reason why those different effects took place when the evaporation seemed to be equally quick and copious. Amongst other substances I tried glass, and found that it generally produced little or no electricity. The water was sometimes poured upon the hot glass, but in general the hot glass was dropped into the insulated water which was contained in a tin cup. However, the difference of effect was found not to be occasioned by those two different modes of proceeding. Having repeated this experiment a great many times, I at last found that the effect depended upon the different nature of the glass. If white and clean flint glass be made red-hot, and in that state be dropped into the vessel of water, a quick evaporation will ensue, and the vessel is electrified positively. If the flint glass be not very clear, there will not be any electricity generated by the evaporation. And, lastly, if the experiment be tried with glass more impure, as that of which wine bottles are made, then the negative electricity will be produced.

"In performing this experiment, it is necessary to take care that no pieces of coal adhere to the glass, which will frequently happen when a piece of glass is heated in a common fire; for in that case negative electricity will be produced by the evaporation, though the best flint glass be used."

*Expansion and contraction.*—The mere expansion of parts produces electricity in various instances; such as the dispersion of powders by projection or blowing; and the electrometer is affected by the same. It is owing to this electrified state of the powders, that several curious phenomena are exhibited by them, which could not otherwise be explained. Thus the configurations which are produced by projecting powders upon an electrophorus, or upon any electrified surface, are owing, in great measure, to this cause; thus also the dust upon the roads when properly attended to is often found to expand itself more than it apparently should, and to assume peculiar movements, in consequence of its actual electrified state, which may be easily discovered by means of a very delicate electrometer. For further particulars respecting this kind of excitation, see the article *ELECTRICAL Experiments*, and the description of Mr. Bennet's gold-leaf electrometer, under the article *ELECTROMETER*. Mr. Cavallo, in his *Treatise on Electricity*, gives the following directions for exciting powders. "Insulate," he says, "a metal plate upon an electric stand, and connect with it a cork-ball electrometer; then the powder which is required to be tried, being held in a spoon, or other thing, at about six inches above

the plate, is to be let fall gradually upon it. In this manner the electricity acquired by the powder, being communicated to the metal plate, and to the electrometer, is rendered manifest by the divergency of the threads; and its quality may be ascertained in the usual manner."

"It must be observed, that if the powder is of a conducting nature, like the amalgam of metals, or sand, &c. it must be held in some electric substance, as a glass phial, a plate of sealing-wax, or the like. Sometimes the spoon that holds the powder may be insulated; in which case, after the experiment, the spoon will be found possessed of the electricity contrary to that of the powder."

It is, however, proper to remark with respect to this kind of excitation, that the production of the electricity is in some measure due to the friction; for in the act of pouring any substance in powder from a plate, a vessel, &c. a degree of friction between the latter and the former must necessarily take place.

*Contact, or juxtaposition.*—That the mere contact of two perfect conductors would generate, or excite electricity, is a discovery of a very late date. Mr. Cavallo seems to have been the first who proved that by dropping a piece of metal upon another, a slight degree of electricity was thereby produced. (See the 4th edition of his *Treatise on Electricity*, published in 1795, third vol. *Experiments on Metallic Substances*.) Mr. Bennet also, independent of Mr. Cavallo's experiments, seems to have a claim to this discovery. The electricity thus produced was so very slight, that it could only be discovered by the nicest methods; but it was the forerunner of a most astonishing discovery. In short Mr. Volta, by repeating the contact of metallic substances, and at the same time exposing them to the action of a saline substance, produced a most powerful electrical instrument, which has opened a new field of ample and promising aspect, and has furnished the chemical philosopher with the most active engine of decomposition.

This, and the other modes of excitation that have been mentioned subsequent to it, *viz.* by means of solution, or effervescence, and by the action of the animal body, cannot be well explained, nor thoroughly understood, without a full, historical, and circumstantial account of that new and admirable branch of electricity, which is now commonly called *Galvanism*; but which in justice ought rather to be called *Voltaism*; and as it would be useless to fill this *Cyclopædia* with repetitions, we must refer our readers to the articles of the two last mentioned denominations, wherein those other modes of excitation are particularly described.

*Excitation of Heat.*—The temperature of bodies is raised either by the approach of a body hotter than themselves, or by the extrication of heat from the bodies themselves, occasioned by some particular action or disposition. The former of these methods of elevating the temperature is a mere communication of heat; for that principle continually tends to disperse itself amongst surrounding bodies, until they all acquire the same degree of temperature. The latter is called the *excitation* of heat, since an elevation of temperature takes place amongst bodies which were not hotter than the surrounding bodies a short time before. Thus, when a person stands before a common fire, heat is said to be communicated to him, but with respect to the fire itself, the heat is said to be excited, or produced by that particular decomposition of fuel which is called combustion. Thus also heat is excited by friction, by the mixture of water with sulphuric acid, and by a great many other

## EXCITATION.

other means; but it is communicated by the rays of the sun.

The means by which various degrees of sensible heat are produced and communicated, are not more than eight; *viz.* 1. Animal heat, or that power in animals which keeps them warm, and enables them to communicate heat to other bodies. 2. Compression. 3. Friction, or percussion of hard bodies. 4. Electricity. 5. Mixture. 6. Fermentation, or putrefaction. 7. The sun's rays; and, 8. The inflammation of fuel. However, by excluding the consideration of the sun's rays for reasons already assigned; by comprehending animal heat, fermentation, and inflammation under the general denomination of decomposition; and by referring the action of electricity to friction; the various modes of exciting heat, which demand our consideration in the present article, may be reduced to four; namely, compression, friction, mixture, and decomposition; and even this number may be diminished by two, since, as it will appear in the sequel, both friction and mixture may be comprehended under the head of compression; for in these two cases the excitation of heat seems to be occasioned by the compression or concentration of the integrant parts. We shall, however, for the sake of perspicuity, treat distinctly of the above-mentioned four modes.

The flattening or stretching of metallic substances, whether it be effected by means of the hammer, or screw presses, or flattening mills, or wire drawing, or any other such like means, is constantly attended with an excitation of heat, and a compression of the metallic substance. The former of these effects is perceived by the feel, or, more accurately, by the thermometer; the latter by an increase of specific gravity in the substance that has been operated upon. Not only the metals, but all other substances that are susceptible of compression, such as wood, cotton, the aerial fluids, &c. are likewise heated by the same means. On the other hand, water, hard stones, and all such bodies as cannot be condensed into a smaller space, at least not in any considerable degree, will not be heated by the above-mentioned means.

The heat, which is thus excited, differs in degree according to the nature of the substance, the violence of the pressure, and the quickness of the operation; thus a metallic substance, powerfully and quickly compressed, becomes hotter than a piece of wood similarly treated, and hotter than if it were pressed gently or slowly; for with a gentle pressure little heat is excited, and when the pressure is applied slowly, the heat is dissipated nearly as fast as it is excited.

A dexterous blacksmith, by giving a dozen or twenty smart strokes with a hammer, to the extremity of a slender iron rod upon an anvil, will render that extremity of the rod visibly red-hot, even in the day light; and this is the way by which several blacksmiths light the fire of their forges when they go to work in the morning. With respect to this operation, Dr. Black, in his Lectures, remarks, that the same extremity of the iron rod cannot be rendered red-hot a second time by hammering, unless it be first annealed, or softened in the fire. "On account," he says, "of this and other facts, I began to suspect that malleability and ductility of metals depend on a certain quantity of latent heat existing in them, which being extricated by hammering, the metals remain rigid, and require to be placed in the fire or annealed, in order to recover that latent heat."

A mixture of oxygen and hydrogen gases, if compressed, takes fire, and explodes with great violence. The mechanical condensation of vapour, and of all the aerial fluids,

is attended with a considerable elevation of temperature. The condensation of common air excites a considerable degree of heat, and, when quickly performed, it fires a variety of combustibles, such as cotton, charcoal previously warmed, tinder, &c.; and upon this principle a curious instrument has of late been contrived, by which a candle or fire may be lighted. It is nothing more than a small syringe, or little condenser, about six inches long, and not much above a quarter of an inch in diameter, (meaning the diameter of its cylindrical cavity.) It has a piston, the rod of which comes out at one end, and a stop-cock at the other end; this stop-cock is not perforated quite through, but only little more than half way, so that its cavity may either be exposed to the external air, or it may be turned towards the cylindrical cavity of the syringe. The operation is performed in the following manner: the piston is first drawn out as far as the extremity of the syringe, a little bit of *amadue*, (more commonly known by the name of German tinder,) is placed into the cavity of the stop-cock, which is afterwards turned towards the cylindrical cavity of the syringe; this done, the piston is pushed in quickly and forcibly, with one smart stroke, by which means the sudden condensation of the air excites a degree of heat sufficient to set fire to the tinder; and in fact if the stop-cock be turned outwardly immediately, after having pushed the piston in, the tinder will be found burning, and a match may be lighted by it.

From a general consideration of the effects of compression, it appears that the caloric, or that principle to which the effects of heat are attributed, is contained within the pores of other bodies, somewhat like water in the cavities of a sponge, and that by compressing the body, part of that caloric is disengaged, and becomes sensible heat. Thus when a mixture of oxygen and hydrogen gases is quickly and forcibly condensed, that operation forces the gases to abandon a quantity of caloric, which becomes sensible heat, and as it cannot be dissipated immediately, raises their temperature to a degree sufficient for their inflammation. This explanation is corroborated by the converse of the above operation, *viz.* by expansion; for when gases are expanded, they absorb an additional quantity of heat, which does not raise their temperature.

Friction is well known to excite heat, the degree of which differs in proportion to the nature of the bodies concerned, and the force which is employed. This effect of friction is so commonly experienced, and so generally used, as to require but little illustration. Rubbing the hands against each other, or against any part of the body in order to excite heat, is a general practice. Filing, turning, grinding, striking a piece of steel against a flint, the motion of the axles of wheels in their holes, &c. are common and well-known instances of friction, which excite heat. In these cases the consideration of two remarkable circumstances forcibly lead us to conclude, that the heat is excited by the compression of the parts of the bodies concerned. One of the circumstances alluded to is, that compression is the necessary consequence of friction; the other is, that such substances as are not compressible, or the compressibility of which is next to nothing, cannot be heated by means of friction.

Thus Dr. Irvine says, in his Lectures, "The most violent agitation of simple fluids, such as water or mercury, will not sensibly affect the thermometer. Heat is produced by agitation on those fluids which are compound, and whose state of existence is changed by the agitation; such as milk, and the solution of certain salts in water."

It is asserted in Nicholson's Journal for June 1808, that  
Dr.

## EXCITATION.

Dr. Joseph Read found that by agitating water in a tin vessel, or in a glass one for a few minutes, the temperature of that fluid was raised about eight degrees, as it appeared from a thermometer left in it all that time. We are, however, strongly inclined to suspect that this apparent result was owing to some fallacy in the mode of conducting the experiment.

It seems, therefore, most probable, that friction produces a compression, and that the caloric is expelled from the bodies concerned, so as to become sensible heat, in consequence of that compression.

The greatest opponent to this hypothesis is count Rumford, who instituted some capital experiments, which are described at large in the *Philosophical Transactions*, and in which he succeeded to set a quantity of water actually a boiling by the friction of metal against metal. In short, the metal submitted to friction was encompassed by water, and air was carefully excluded from the surfaces in motion; yet the water became hot, and was kept boiling a considerable time. In this experiment the only obvious source of caloric, from without, as the count imagines, was through the borer employed to produce the friction; if it be true, that the water could not at the same instant be in the act of giving out and receiving heat. Mr. Wm. Henry (*Trans. of the Manchester Society*, vol. v. p. 2.) reasoning upon this experiment of count Rumford, says, "I cannot admit that the argument is demonstrative in proving the evolved caloric not to be derived from external substances; for no absurdity is implied in supposing that a body may be receiving caloric in one state, and giving it out in another." Thus these gentlemen seem to exclude the action of the compression between the metallic bodies, which is occasioned by the friction, and upon which the whole effect seems most probably to depend.

With respect to this excitation of heat by means of friction, two useful practical considerations naturally occur; *viz.* to determine which kinds of friction are capable of producing the greatest degree of heat, and in what manner the heat which arises from the friction of the parts of machinery in general, may be prevented.

The production of heat, and of actual fire, by the friction of wood against wood, seems to be the first that occurs to the human being, since the materials necessary for it are to be met with every where, and do not require any previous preparation, excepting a trifling adaptation of shape. In fact all rude nations that have any notion of fire, light their fires by this means. For this purpose, a piece of wood is laid flat nearly in an horizontal situation, and another slender piece of wood is rubbed with one extremity backward and forward over the surface of the former, until it excites heat enough to set fire to the dust that has been abraded from the wood itself by the friction. Otherwise a blunt pointed piece of wood is held perpendicularly over an horizontal piece, with its point in a little cavity on the surface of the latter, and is worked therein, like a drill, by rolling it between the hands of the operator, after the manner of a chocolate mill. Though this operation may at first sight appear to be easy and simple, and though it be readily performed by the individuals of rude nations; yet certain it is that the practice of it is not easily acquired; and in fact there are very few persons in Europe who are able to succeed in it. Professor Bartholdi says, that the best kinds of wood for this purpose are, box-wood rubbed against mulberry, or laurel against poplar, or against ivy. But the use of this mode of exciting heat amongst all civilized nations is superseded by the incomparably easier, and much more effectual method, of striking a piece of steel against the edge

of a siliceous stone. In this operation small particles of the steel are violently compressed and scraped off in an ignited state, so as to fire tinder, gun-powder, &c. The very common and general use of this method, for domestic convenience, for gun-locks, &c. renders any farther descriptions of it perfectly useless.

We have ventured to refer the excitation of heat by electricity, to friction, in consideration that electricity does not excite any heat, unless it is actually passing through bodies, which in some measure obstruct its free passage. But we must refer the reader for the farther consideration of this matter to the articles which relate to electricity.

It is a matter of great importance in mechanics to prevent, or, at least, to diminish the heat which is excited by the friction of the parts of machinery in general; and for this purpose the common practice is to interpose something of a lubricating quality between the contiguous parts of machines, *viz.* something which may hinder the too intimate contact of the parts, and whose particles are easily separated from each other. On various considerations olive oil has been found superior to any thing else in metallic machinery, and especially in watch or clock-work, when steel works in metal or in hard stone. Where wood and metals work against each other, hog's lard, or mutton-suet or such other fat or grease, is mostly used; and when wood works against wood, then the powder of black lead is found to be the most useful.

The heat which is excited by the mixture of certain bodies, comes next under consideration: the instances of this kind are very numerous, and different degrees of heat may be excited by this means, as far as actual inflammation. The following are selected. If spirit of wine be mixed with water, the mixture will instantly become hot enough to be perceived not only by means of the thermometer, but likewise by the mere application of the human hand. This heat will be gradually dissipated, so that in a few minutes' time that mixture will be found to have acquired the temperature of the surrounding bodies. On mixing a quantity of the strongest sulphuric acid with an equal quantity of water, a degree of heat is excited which exceeds that of boiling water. If a mixture of nitric and sulphuric acids be poured upon an inflammable essential oil, such as oil of cloves, oil of turpentine, &c.; the latter is thereby so heated as to burst out in flames. Water mixed with quicklime excites a considerable degree of heat. There is a kind of earth found in Derbyshire, which is called *blackwad*. If a quantity of this earth, as about half a pound or more of it, be sprinkled over with linseed oil, and be then left undisturbed, and exposed to the air, about an hour after it will be found in a state of incandescence, burning somewhat like small coal.

In all the cases of the excitation of heat by the mixture of fluids, two remarkable circumstances deserve particular consideration. One is that the heat will be excited only when the fluids have a chemical action upon each other, such as between acids and water, spirituous liquors and water, &c.; whereas, if oil be mixed with water, or water with quicksilver, no heat will be excited, because no real mixture will take place among these bodies. The other circumstance is, that whenever heat is excited by the mixture of fluids, an incorporation, or a concentration of the substances is observed; for it is always attended with a diminution of bulk. Thus a pint of alcohol and a pint of water, mixed together, will measure less than two pints. These circumstances seem to indicate, that the affinity, or the mutual attraction of the particles of the bodies concerned, occasions

sions a kind of compression, in consequence of which a certain part of the caloric is forced out, and becomes sensible heat.

The fourth cause of the excitation of heat is decomposition; and under this head we must comprehend the origin of animal heat, fermentation, putrefaction, combustion, and all other processes in which the heat is manifestly excited in consequence of the decomposition of compound bodies. But as these processes will be found treated at large under the articles of their peculiar denominations; we shall here only add a few remarks on the heat which is produced by decompositions in general. In short it seems that the caloric, like several other principles, enters more or less into the formation of compound bodies, and that in the decomposition of these bodies, where certain principles are set at liberty, and other new combinations ensue, the caloric also undergoes its changes; *viz.* it is expelled from certain bodies, and is either set entirely at liberty so as to become sensible heat, or is partially reabsorbed, in which latter case but little heat is manifested. This liberation of caloric is sometimes effected slowly, as in the process of animal life, in fermentations, &c. or it proceeds so quickly and abundantly, as to occasion actual inflammation. By the concurrence of various favourable circumstances it happens, not unfrequently, that decompositions and spontaneous inflammations take place among bodies, which, in general, are not capable of producing such phenomena. Thus, vegetable substances that have undergone torrefaction, being kept in sacks of cloth in contact with the ambient air, as coffee, the meal of grain, French beans, &c. have sometimes been known to take fire. The like effect is also produced by the generation of sulphurated and phosphorated hydrogen gas. The cause of subterraneous fires and volcanoes has in great measure been attributed to the decomposition of pyrites, or metallic sulphurets, buried in the interior of the earth. These masses of pyrites are decomposed by the contact and concurrence of water and air; and the decomposition is always accompanied by a great extrication of caloric, and a disengagement of a very inflammable gas, called *sulphurated hydrogen gas*. This gas is inflated at an elevated temperature, and communicates the inflammation to other combustibles that may be at hand.

With respect to the heat which is produced in combustions, several questions of economical use may be asked, such as the determination of the cheapest and most economical mode of employing fuel, the method of preventing the dissipation of heat, &c. but these particulars will be found under the articles FIRE, FUEL, and HEAT.

EXCITEMENT, in Dr. Browne's system of *Medicine*, nearly synonymous with life. See EXCITABILITY.

EXCLAMATION, or ECPHONESIS, in *Rhetoric*, a figure, wherein, by raising the voice, and using an interjection either expressly or understood, we testify an uncommon ardour, commotion, and passion of mind; and express the magnitude of the thing, or the importance of the occasion.

Such is, "O heavens! O earth!" &c. such also is that of Cicero against Cataline: "O times! O manners! this the senate knows, the consul sees—and yet he lives! Lives, said I? nay, and comes into the senate!"

In English the interjections O! or oh! alas! or good God! are generally adjoined in an exclamation. In Latin they use O! heu! eheu! ah! vah! pro superi! pro superum atque hominum fidem!" Sometimes, however, the interjection is understood, as, Woe is me! Miserum me! hocce seculum!

Cicero uses this figure to express a variety of passions. It often denotes resentment or indignation. Thus, after

his return from banishment, he exclaims, (*Pro Sext. c. 12.*) "O mournful day to the Senate and all good men; calamitous to the state, afflictive to me and my family; but glorious in the view of posterity!" At other times it is used to express disdain or contempt. Thus, speaking of Pompey's house, which was bought by Mark Antony, he says, (*Philipp. II. c. 12.*) "O consummate impudence! Dare you go within that house! Dare you enter the venerable threshold, and shew your audacious countenance to the tutelary deities which reside there?" It is no less adapted to express grief. Thus, Cicero says of Milo, (*Pro Milone, sub fin.*) "O that happy country, which shall receive this man! ungrateful this, if it banish him! miserable, if it lose him!" It also serves to express admiration, as when Cicero, in compliment to Cæsar, says, (*Pro Ligur. c. 2.*) "O admirable clemency! worthy of the greatest praise, the highest encomiums, and most lasting monuments!" It has its use also in ridicule and irony. Thus Cicero, in his oration for Balbus, deriding his accuser, exclaims, "O excellent interpreter of the law! master of antiquity! corrector and amender of our constitution!" The sacred writers sometimes use it by way of intreaty or wish, *Ps. lv. 6.*, and at other times in exultation and triumph, so St. Paul exclaims, (*1 Cor. xv. 25.*) "O death, where is thy sting! O grave, where is thy victory!" It is frequently joined, as in some of the preceding instances, with the figure "Interrogation." It generally follows the representation of the thing which occasions it; though it is sometimes used to introduce it, and thus it serves to prepare the mind by exciting its attention.

EXCLUSION, the act whereby a person or thing is excluded, *i. e.* shut out or set aside. A crown imports an exclusion from the papacy: he appointed a stranger his heir, in exclusion of his own relations.

Great efforts were made towards the close of the reign of king Charles II. to procure a bill of exclusion, for setting aside the duke of York, the king's brother, on account of his being a papist. See CROWN.

EXCLUSIONS, in *Mathematics*. The method of exclusions, is a way of coming at the solution of problems (in numerical cases) by previously ejecting, or excluding out of consideration, such numbers as are of no use in solving the question; whereby, of consequence, the process may be regularly and judiciously abbreviated.

EXCLUSIVE, is sometimes used adjectively, for the force or power of excluding; as, a patent carries with it an exclusive privilege.

Sometimes it is also used adverbially; as, he sent him all the Gazettes, from N<sup>o</sup> 195, to N<sup>o</sup> 300 exclusive; *i. e.* all between those two numbers, which themselves were excepted.

EXCLUSIVE Propositions, are those wherein the predicate so agrees with the subject, as to agree with no other. See PROPOSITION. *E. gr.* Virtue alone makes nobility: nothing else renders a man truly noble.

EXCÆCARIA, in *Botany*, from *excæco*, to deprive of sight, because, according to Rumphius, the sailors who first landed on the islands of the East Indies, where this tree grows, were greatly incommoded, and sometimes even entirely blinded, by the acrid juice which spirted forth, as they felled the wood for burning. Linn. Gen. 515. Schreb. 677. Juss. 390. Gært. t. 108. Class and order, *Diacia Triandria*. Nat. Ord. *Tricocca*, Linn. *Euphorbia*, Juss.

Gen. Ch. Male, *Cal.* Catkin cylindrical, covered with florets. *Cor.* none. *Stam.* Filaments three, thread-shaped; anthers roundish. Female, *Cal.* Catkin as in the male. *Cor.* none. *Pist.* Germen superior, roundish, somewhat triangular;

angular; styles three; stigmas simple. *Peric.* Capsule three-lobed, smooth, of three valves, each marked with a furrow, and three cells. *Seeds* solitary, smooth.

Ess. Ch. Male, Catkin naked. Perianth none. Corolla none. Female as in the male. Styles three. Capsule three-lobed. Seeds solitary.

*E. Agallocha.* Linn. Sp. Pl. 1451. (Arbor exœcans; Rumph. Amb. v. 2. 237. t. 79, 80.) Native of rocky, dry, and sandy places about the coast in Amboina and other East Indian islands, flowering in January and February, as well as occasionally at other seasons. It forms a crooked inelegant tree. The *leaves* are alternate, elliptical, bluntnish, smooth, more or less waved or bluntly crenate. *Catkins* cylindrical, lateral. *Capsules* the size of a pea. The acrid milk with which the tree abounds, causes the inhabitants of the countries where it grows to hold it in abhorrence; but Rumphius says it is chiefly dangerous to the eyes. The bark, as well as the milk, are used in medicine, being powerfully purgative. There seems to be no propriety in applying the Greek name *αγαλλοχον*, from Dioscorides, to this tree.

How far the Cammetti, Rheede Hort. Malab. v. 5. 89. t. 45, is a distinct species from the above, we have not materials to decide. Its *leaves* are more pointed and less distinctly waved. Koenig gathered it by the sea side on the coast of Coromandel, in low ground, overflowed during the rainy season, which does not agree with what Rumphius relates of the foregoing.

Loureiro describes what is probably another species, by the name of *E. cochinchinensis*, in p. 612. of his Flora Cochinch. This, he says, has beautiful shining *leaves*, red underneath, for the sake of which it is cultivated as an ornamental shrub. Its qualities are astringent and glutinous, nor did he ever hear of its being hurtful to the eyes.

**EXCOMMUNICATION**, an anathema, or ecclesiastical censure, and punishment; whereby a heretic is cut off from the society of the faithful, or an obstinate sinner from the communion of the church, and the participation of the sacraments.

This censure of excommunication was originally instituted for preserving the purity of the church; but ambitious ecclesiastics converted it by degrees into an engine for promoting their own power, and inflicted it on the most frivolous occasions.

The power of excommunication properly belongs to the bishop; but he may delegate it to any grave priest, with the chancellor.

Every excommunication should be preceded by three public admonitions, two days at least distant from each other; but this is to be understood of excommunications imposed by the ecclesiastical judge; for those imposed by the law are incurred to all intents and purposes the moment the action is committed.

These latter are called excommunications *by the canon*, or *late sententiæ*; and are so very numerous, that it would be difficult even for the best canonists to give an exact list of them; there are fifty in the Clementines; twenty in the bull *Cana Domini*, &c. Wilkins's Mag. Brit. Conc. vol. iv. p. 664. Rebuffe, on the Concordat, reckons up sixty penalties accruing upon excommunication.

Excommunication is founded on a natural right which all societies have, of excluding out of their body such as violate the laws thereof.

Excommunication is either *major* or *minor*, i. e. *greater* or *less*; the first, which is that understood when we say, simply, excommunication separates, or cuts off, the delinquent, not only from the sacraments, but from all communion and fellowship with other Christians. The second,

or lesser, only excludes from the participation of the sacraments.

The greater excommunication, called also *ab homine*, is when a prelate, or his deputy, excommunicates any man personally, and interdicts him all society with the faithful, all use of sacraments, &c.

In the ancient church, the sentences of the greater excommunication were solemnly promulged four times in the year, with candles lighted, bells tolling, the cross, and other solemnities.

The lesser excommunication is incurred *pleno jure*, by having any communication with a person excommunicated in the greater excommunication. And this too imports a privation of communion, but not an interdiction from entering the church, or having commerce with the faithful.

Anciently, the excommunicated were obliged to procure absolution from their bishop, and make satisfaction to the church in forty days' time; otherwise they were compelled to it by the secular judge, by a seizure of their effects, imprisonment of their persons, &c. (See **EXCOMMUNICATIO Capiendo**.) In France they were allowed a whole year.

By an edict of St. Louis, in the year 1228, vassals, tenants, &c. were dispensed, or freed from the oath of fidelity, homage, &c. they had taken to their lords, or superiors, when excommunicate, till they had made their submission.

In Spain, to this day, a person who is not absolved from his excommunication in a year's time is deemed a heretic. There was a time, when the people were fully convinced, that the bodies of excommunicated persons, unless they were first absolved, would not rot, but remain entire for several ages, a horrible spectacle to posterity! as is attested by Matthew Paris, and other writers. And the Greeks are still of the opinion, and affirm, they have many proofs thereof; as is shewn by Du-Cange, from the testimony of a vast number of authors.

By the laws, an excommunicated person was not to be buried, but the body flung into a pit, or covered with a heap of stones; which were called *imblocare corpus*. And by the rubric, in the Book of Common Prayer, the burial office shall not be read for any that die excommunicated. See **FUNERAL**, &c.

In the ancient church, there were diverse degrees of excommunication. In effect, excommunication did not always import an interdiction of the sacraments; but frequently, a separation, or kind of schism, between the several churches, or a suspension of spiritual communication between the bishops. But afterwards the occasions of excommunications growing more frequent, they began to use it with less circumspection and reservedness.

In the ninth century the ecclesiastics were continually making use of this spiritual weapon, to repel any violence or affronts offered them; and time and familiarity rendering offenders more and more obdurate, they proceeded, by degrees, to rigours unknown to antiquity; as the excommunicating of whole families, or provinces; prohibiting the exercise of all religion therein; and even accompanying the excommunications with horrible ceremonies, and direful imprecations.

In the tenth and eleventh centuries, the severity against the excommunicated was carried to its highest pitch: nobody might come near them, not even their own wives, children, or servants; they forfeited all their natural legal rights and privileges, and were excluded from all kinds of offices. Thus was an excommunicated king reduced to the condition of a private man. By thus stretching the power of the church to extravagance, they rendered it contempti-

ble. Gregory VII. tempered it a little; exempting the wives and children of excommunicated persons from incurring excommunication by holding conversation with their husbands and parents.

To render the excommunicated still more odious, the priest was obliged to stop, and break off divine service, if an excommunicated person entered the church; nothing of which averſion is any where diſcovered in the practice of the primitive church. At preſent we have but little of the terror or reſpect of our forefathers for excommunication; and it is even judged, and proclaimed, an abuſe, whenever impertinently employed.

The form of excommunication in the Romiſh church, as related by Fevret, is to take lighted torches, throw them on the ground with curſes and anathemas, and trample them out under-foot to the ringing of the bells.

“Auctoritate Dei Patris omnipotentis, et Filii, et Spiritus Sancti, et beatae Dei genetricis Mariae, omniumque sanctorum, excommunicamus, anathematizamus, et a limitibus sanctae matris ecclesiae sequestramus illos malefactores, N. consentaneos quoque et participes; et nisi resipuerint, et ad satisfactionem venerint, sic extinguetur lucerna eorum ante viventem in saecula saeculorum. Fiat: Amen: Amen: Amen.” Ex Emendat. Leg. Will. Conquest.

We have now none of this folly; the sentence is gravely read, and the person remains excommunicated without farther ceremony. See the form of excommunication of the English church in Concilia M. Brit. et Hib. vol. iv. p. 663, &c.

Petrus Bleſenſis aſſures us, that in England it was anciently the practice only to excommunicate ſuch as had killed an eccleſiaſtic; whereas they were put to death who had killed a layman. But the reaſon was, they held excommunication a greater puniſhment than death.

The cauſes with us are contempt of the biſhop's court, hereſy, neglect of coming to church, and of receiving the ſacrament, incontinency, adultery, ſimony, &c.

But if the judge of any ſpiritual court excommunicates a man for a cauſe of which he hath not the legal cognizance, the party may have an action againſt him at common law, and he is alſo liable to be indicted at the ſuit of the king. (2 Inſt. 623.) With us by the common law an excommunicated perſon is diſabled to do any act, that is required to be done by one that is “*probus et legalis homo*.” He cannot ſerve on juries, cannot be a witneſs in any court, and cannot bring an action, either real or perſonal, to recover lands or money due to him. (Litt. § 200.) Beſides, if, within 40 days after the ſentence has been publiſhed in the church, the offender does not ſubmit and abide by the ſentence of the ſpiritual court, the biſhop may certify ſuch contempt to the king in chancery; upon which there iſſues out a writ *De Excommunicato capiendo*; which ſee.

We have inſtances of biſhops, who have pronounced formal excommunications againſt caterpillars, and other inſects, after a formal juridical proceſs againſt them, wherein thoſe animals were allowed an advocate, and proctor to defend their cauſe. See EXORCISM.

Fevret relates divers inſtances of ſuch excommunications againſt rats, mice, and other animals, for infeſting a country. See the form of theſe excommunications in that author, Trajté de l'Albus.

In the ancient church there were two different kinds of excommunications in uſe; the one called *medicinal*, whereby perſons convicted of a crime by their own confeſſion, were removed from communion; the other, called *mortal*, was fulminated againſt rebels, who perſiſted obſtinately in their errors and impieties.

The power of excommunicating was lodged in the whole church in general; that is, the biſhops and prieſts had the adminiſtration thereof by and with the conſent of the people, which was practiſed even in St. Cyprian's time. But afterwards they ceaſed to conſult the people about the matter; the biſhop and clergy arrogated the whole power to themſelves. Recourſe, however, might ſtill be had to the ſynod of the province, to judge of the validity of an excommunication.

EXCOMMUNICATION was alſo practiſed among the Jews, who uſed to expel from their ſynagogue ſuch as had committed any grievous crime. See the Goſpel according to St. John, ix. 22. xii. 42. xvi. 2. And Joſeph. Antiq. Jud. lib. ix. cap. 22. and lib. xvi. cap. 2.

The Eſſeni, when excommunicated, durſt not ſo much as receive food at any perſon's hand, for fear of violating their oath, but contented themſelves to live on herbs; inſomuch that they frequently periſhed and died for want. See Joſeph. de Bell. lib. ii. cap. 12.

Godwyn, in his Moſes and Aaron, diſtinguiſhes three degrees, or kinds, of excommunication among the Jews.

The firſt he finds intimated in St. John ix. 22. The ſecond in St. Paul Epiſt. 1 Cor. v. 5. And the third, in the 1ſt Ep. to Corinth. xvi. 22. See NIDIVI.

The rule of the Benediſtines gives the name excommunication to the being excluded from the oratory, and the common table of the houſe in our inns of court called *diſcommuning*. This was the puniſhment of ſuch monks as came too late.

EXCOMMUNICATION, or a being ſecluded, or cut off from a participation in the myſteries of religion, was alſo in uſe under paganiſm.

Such as were thus excommunicated were forbidden to aſſiſt or attend at the ſacrifices, or to enter within the temples; and were afterwards delivered over to the dæmons and furies of hell, with certain imprecations; which was called among the Romans, *diris devovere*. See EXECRATION.

The Druids, among the ancient Britons and Gauls, likewiſe made uſe of excommunication againſt rebels; and interdicted the communion of their myſteries to ſuch as reſuſed to acquieſce in their deciſions. See DRUIDS.

That this is the true origin of the extenſive and horrid influence of the European and papal excommunication, will appear evident by the following paſſage of Cæſar, De Belló Gallico, lib. vi. cap. 13. “*Si qui aut privatus aut publicus Druidum decreto non ſtetit, ſacrificiis interdicunt. Hæc pœna apud eos eſt graviffima. Quibus ita eſt interdictum, in numero impiorum et ſceleratorum habentur, ab iis omnes decedunt, aditum eorum ſermonemque deſugiunt, ne quid ex contagione incommodi accipiant; neque iis petentibus jus redditur, neque honos ullus communicatur.*”

EXCOMMUNICATO CAPIENDO, ſo called from its effects, or *Significavit*, thus denominated from the biſhops' certificate, a writ directed to the ſheriff, for the apprehenſion of one who ſtands obſtinately excommunicated the ſpace of forty days.

Such a one not ſeeking abſolution, hath, or may have, his contempt certified into the chancery; whence this writ iſſues for taking him up and imprifoning him in the county gaol, without bail or mainprize, until he is reconciled to the church, and ſuch reconciliation is certified by the biſhop.

EXCOMMUNICATO Deliberando, is a writ directed to the under ſheriff, for the delivery of an excommunicated perſon out of priſon; upon certificate of the ordinary of his conformity to the eccleſiaſtical juriſdiction. F. N. B. 62.

EXCOMMUNICATO Recipiendo, is a writ whereby perſons excommunicated,

excommunicated, being for their obstinacy committed to prison, and unlawfully delivered from thence before they have given security to obey the authority of the church, are commanded to be fought for and laid up again.

**EXCORIATION**, in *Surgery*. A part is said to be excoriated, when it is deprived of its cuticle, by reason of inflammation; the action of irritating matter, or of stimulating substances, &c. applied to the skin.

Very superficial ulcerations are, also, frequently denominated excoriations.

In consequence of inattention to cleanliness, and not occasionally washing away the sebaceous secretion, which is naturally produced under the prepuce, the matter acquires an irritating acrid quality, brings on inflammation all round the corona glandis, followed by extensive excoriations and suppuration. This sort of case is seriously annoying to the patient, on account of the violent itching, and troublesome soreness, which always attend the complaint. The disorder has sometimes been named the *falsè gonorrhœa*, and the patient is often rendered very uneasy in his mind by an apprehension of the affection being venereal. Indeed, ignorant and careless practitioners have occasionally mistaken mere excoriations for chancres, and, quite improperly, have prescribed a course of mercury.

The proper treatment consists in washing away all the acrid secretion under the prepuce with some soap-suds; injecting under the same part, four or five times a day, the saturnine lotion; and keeping linen, wet with this application, round the extremity of the penis. The excoriations, if very bad, are to be dressed with the saturnine ointment. The prepuce, if much swelled, and in a state of phymosis, should have two or three leeches put upon it; but the principal means of cure is attention to keeping the parts clean, and tenderly washed with plenty of soap once or twice a day. As in all other cases of inflammation the bowels ought to be kept open.

Excoriation of the nipples is a most distressing complaint. It is more common in the first, than the subsequent nursings, and when independent of any disease in the child's mouth, is owing to the irritation occasioned by the suction.

In many instances, a cure may be effected by bathing the parts with a little port wine, or brandy. A more effectual remedy is said to be the tincture of opium.

**EXCORTICATION**, the act of stripping off the cortex or bark from any thing; called also decortication.

**EXCREMENT**, in *Chemistry*. See **FECES**.

**EXCREMENT**, in *Physiology*, is the residue of our food, after the nutritious particles have been extracted from it, and it has undergone certain changes by its residence in the large intestine. See **DIGESTION**.

**EXCREMENT** is also attributed, by way of analogy, to plants. Thus gums, diverse juices, balsms &c. issuing spontaneously from their respective trees, are sometimes called excrements.

**EXCRESCENCE**, in the language of *Surgery*, implies a preternatural protuberance, or any morbid growth, which projects out of the substance or surface of a part. When the disease is involved in the surrounding flesh, though it may be attended with a considerable swelling, it does not rank as an excrescence, which word essentially signifies that the tumour, or whatever the disease is, grows out of the part. Funguses, polypi, and warts of all kinds, are very often, and with strict propriety, denominated excrescences.

Excrescences, of the nature of warts, are particularly apt to grow about the anus. Some of them are generally regarded by surgical authors as venereal complaints, because

they sometimes get well under a course of mercury. This, however, is a very fallacious criterion of a disease being syphilitic; for mercury is a cure for numerous affections besides venereal ones. Some surgeons have doubted whether there is any such thing as a really venereal excrescence; and as far as our observations extend, all those warty growths which arise about the anus and perineum, and are commonly reputed to be of a syphilitic nature, may be cured upon the same principles as any other ordinary tumours, not of a specific kind.

Excrescences in general, not being original parts of the body, are known to be weak in the vital power, and to be incapable of bearing the action of such stimulating applications as would not destroy a part, which may be said to enter into the natural composition of the body. Hence it is, that sprinkling on warty excrescences a powder, consisting of favin and ærugo æris, in equal proportions, generally effects a cure. The swellings are partly diminished by absorption, and partly by sloughing. We have never seen about the anus any excrescences which could withstand this application.

But the plan which we particularly recommend to be adopted, when such excrescences are large and numerous, as they frequently are, is to remove them at once with a knife, or a pair of scissors. When they grow from a narrow neck, their destruction might be accomplished by tying them with a ligature. The latter method, indeed, is often practised by surgeons who are fearful of hæmorrhage, or whose patients have a remarkable dread of a cutting instrument, even in cases in which the object could be fulfilled much more easily, and with less pain, by means of excision; that is to say, in examples in which the base of the swellings is rather broad. Indeed, where the excrescences are connected with the skin by a wide root, the mode of removing them with a ligature becomes exceedingly troublesome and painful; for the practitioner is first under the necessity of introducing, through the centre of their base, a needle armed with a double ligature. The needle being cut off, one ligature is then to be firmly tied over one side of the root of the tumour, and the other over the opposite one. In this manner the supply of blood to the excrescence is suppressed, and the part sloughs away. Sometimes when the base of the disease is very broad, and the ligature has not been applied with due tightness, it becomes necessary to apply another one, the doing of which is attended with as much, if not more, pain than the first operation.

Upon the whole, when the excrescences are small, we prefer stimulating them with the powder of favin and ærugo æris; when they are large, we recommend extirpating them with a cutting instrument.

**EXCRETION**, from *excerno*, *I throw off*, or *separate*, is the separation of any supposed noxious matter from the blood in any of the organs of the animal body. The process itself is not essentially different from that of secretion. But the latter term is applied to those substances which, when formed, are applied to useful purposes in the animal economy. Thus the mucus of mucous membranes imparts to them a necessary moisture, and defends them from the action of the foreign matter which comes in contact with them; the serous exhalation of serous membranes preserves them constantly smooth and polished, and therefore in a fit state for their opposed surfaces to move without any obstacle, &c. The excretions are matters supposed to be noxious to the body, and to be separated on that account, as the urine, bile, perspiration, &c. The matters voided from the large intestine, consisting of the residue of our food, are often called the alvine excretions.

EXCRETORY, is applied to certain little ducts or vessels in the fabric of the glands.

Excretory ducts are the tubes through which the humours separated in the several glands are emitted or discharged out of the gland, into some convenient receptacle or emanatory.

A capillary artery, to which a capillary vein is joined, with an excretory duct, convolved or wound together, make up the body of the glands, the organs of secretion. The excretory ducts spring from the extremities of the arteries and veins, and carry off a liquor separated from the blood. Drake:

The lymphatic glands have either lymphæducts for their excretory ducts, or lacteal vessels, as in the mesentery. Idem.

EXCURSION, in *Astronomy*. See ELONGATION.

EXCURSION, *circles of*. See CIRCLES.

EXCUSABLE HOMICIDE. See HOMICIDE.

EXCUSATI, in *Church History*, a term used to denote slaves, who, flying to any church for sanctuary, were excused and pardoned by their masters; but these were obliged to take an oath to that purpose, before they could have them again; and if they broke the oath, they were punished and fined as persons guilty of perjury.

EXDORF, in *Geography*, a town of Germany, in the county of Henneberg; 7 miles S.E. of Meinungen.

EXE, a river in England, has its origin among the wild eminences of Exmoor, in the western corner of Somersetshire, and after uniting with the Barle, enters the confines of Devonshire, near Exe bridge; thence flowing near Bampton, it sinks into a rich wooded vale, and passing Tiverton, has its current increased by the streams of the Loman. Soon after, the Creedy, from Crediton, in the north-west, and the Culm, or Columb, from Cullumpton, in the north-east, intermingle their waters with the Exe, and the vale expanding, opens into a beautiful plain, encircled by towering eminences, clothed with wood. Passing Exeter, the river proceeds through a fine range of meadows to Topsham, where meeting the tide, and suddenly widening to an extent of more than a mile, it becomes navigable for vessels of several hundred tons burthen. Hence spreading into a grand estuary, it rolls onward; but its direct course being impeded by a vast sand-bank, called the Warren, it winds to the eastward, and flows into the British channel near Exmouth, its whole course being about 60 miles. See CANAL.

EXEA DE LOS CAVALLEROS, an inconsiderable town of Spain in the province of Aragon, seated between two rivulets, in the northern part of the province. Its surname commemorates the bravery of some French and Gascogne cavalry, when Alphonso I. king of Aragon, took it from the Moors. N. lat. 42° 6'. W. long. 1° 9'.

EXEAT, in *Church Discipline*, a Latin term used for a permission which a bishop grants a priest to go out of his diocese; or an abbot to a religious, to go out of his monastery.

The word is also used in several great schools for leave given a scholar or student to go out. His master has given him an exeat.

EXECRATION, EXECRATIO, among the *Ancients*, a kind of punishment, consisting of direful curses and marks of infamy. Livy relates an instance of it, which was used against Philip king of Macedon, by the Athenians. A general assembly of the people being called, they made a decree, that all the statues and images of that king, and of all his ancestors, both of the male and female sex, should be demolished, and their very names rased; that all the festivals, sacred rites, priests, and whatever else had been instituted in

honour of him, should be profaned; that the very place where there had been any monument or inscription to his honour, should be detestable, and that nothing should be set up, or dedicated in them, which could be done in clean places; and, lastly, that the public priests, as often as they prayed for the Athenian people, allies, armies, and fleets, should as many times detest and execrate Philip, his children, kingdom, land, and sea forces, and the whole race and name of the Macedonians.

Cornelius Nepos, in his life of Alcibiades, calls it *devotion*.

At the taking or demolishing of a city, it was frequent to pronounce direful curses and execrations upon any person who should endeavour to rebuild it; which some imagine was the reason that Troy could never be raised out of its ashes, though several persons attempted it, being devoted to eternal and irreparable ruin by Agamemnon. This seems to have been a very ancient custom, and derived from the Eastern nations; for we find Joshua, at the destruction of Jericho, to have fixed an imprecation upon the person who should rebuild it, which was thought to be accomplished in Hiel the Bethelite many ages after. Potter, *Archæol.* tom. ii. p. 97.

EXECREBRONCHOS, in *Surgery*, from *εξερα*, to abound, and *βρονχος*, a throat, a term which probably signified a swelling of the thyroid gland, which affection is now almost always named bronchocele.

EXECUTANT, *Fr.* in *Music*, a participle used substantively. A musician or performer who executes his part in a band, in the same sense as concertant implies a performer in a concert. See CONCERTANT, EXECUTER, and EXECUTION.

EXECUTED *Contract, Estate, Fine, and Remainder*. See the substantives.

EXECUTER, *Fr.* to execute, play, sing, or perform a composition, or piece of music, in all its parts, whether vocal or instrumental, and to let every note and passage be heard agreeable to the notation in the score.

As music is an object for the ear, it can only be judged by its effects in the execution. Many pieces of counterpoint look correct and learned on paper, which no real judge can hear without disgust; and others that look thin, simple, and common, which in the execution afford the highest pleasure, by unexpected effects. Vulgar composers, attentive to symmetry and the filling up all the parts, often appear to be great contrapuntists, while they are judged merely by the eyes; and such composers often have the address to employ so many different instruments, and such a number of parts in their music, that it is with great difficulty a sufficient band can be collected to do it justice in the execution. Rousseau.

EXECUTION, the act of executing, *i. e.* of accomplishing, finishing, or achieving any thing to be done.

We say, the execution of a testament; of a law; of a treaty; of a building, or the like.

EXECUTION, in *Common Law*, signifies the last performance of an act; as of a writ, a judgment, or the like.

EXECUTION of a judgment, denotes the putting of the law in force, or it is the obtaining the possession of any thing recovered by judgment of law.

This is performed in various ways, according to the nature of the action upon which it is founded, and of the judgment which is had or recovered. If the plaintiff recovers in an action real or mixed, whereby the seisin or possession of land is awarded to him, the writ of execution shall be an *habere facias seisinam*, or writ of seisin, of a freehold; or an *habere facias possessionem*, or writ of possession,

## EXECUTION.

of a chattel interest. (Finch. L. 470.) These are writs directed to the sheriff of the county, commanding him to give actual possession to the plaintiff, of the land so recovered; in the execution of which the sheriff may take with him the *posse comitatus*, or power of the county, and may justify breaking open doors, if the possession be not quietly delivered. But if it is peaceably yielded up, the delivery of a twig, a turf, or the ring of the door, in the name of seisin, is sufficient execution of the writ. Upon a presentation to a benefice recovered in a *quare impedit*, or assise of *darrein presentment*, the execution is by a writ *de clerico admittendo*; directed not to the sheriff, but to the bishop or archbishop, and requiring him to admit and institute the clerk of the plaintiff. In other actions, where the judgment is, that something special be done or rendered by the defendant, then, in order to compel him so to do, and to see the judgment executed, a special writ of execution issues to the sheriff, according to the nature of the case. As, upon an assise of nuisance, or *quod permittat proferre*, where one part of the judgment is *quod nocumentum amoveatur*, a writ goes to the sheriff to abate it, at the charge of the party, which likewise issues even in case of an indictment. (Comb. 10.) Upon a replevin, the writ of execution is the writ *de retorno habendo*; and if the distress be eloiigned, the defendant shall have a *capias in withernam*; but on the plaintiff's tendering the damages, and submitting to a fine, the process in *withernam* shall be stayed. (2 Leon. 174.) In detinue, after judgment, the plaintiff shall have a *distringas*, to compel the defendant to deliver the goods, by repeated distresses of his chattels, (1 Roll. Abr. 737. Ralt. Entr. 215); or also a *scire facias* against any third person in whose hands they may happen to be, to shew cause why they should not be delivered; and if the defendant still continues obstinate, then (if the judgment hath been by default or on demurrer) the sheriff shall summon an inquest to ascertain the value of the goods, and the plaintiff's damages; which (being either so assessed, or by the verdict in case of an issue, Bro. Abr. tit. *Damages*, 29.) shall be levied on the person or goods of the defendant.

Executions in actions, where money only is recovered, as a debt or damages, (and not any specific chattel,) are of five sorts: either against the body of the defendant; or against his goods and chattels; or against his goods and the profits of his lands; or against his goods and the possession of his lands; or against all three, his body, lands, and goods. The first of these species of execution is by writ of *CAPIAS ad satisfaciendum*, which see. This writ is an execution of the highest nature, inasmuch as it deprives a man of his liberty, till he makes the satisfaction awarded. When a defendant is once in custody upon this process, he is to be kept in *arcta et salva custodia*; and if he be afterwards seen at large, it is an *escape*, which see; and the plaintiff may have an action thereupon against the sheriff for his whole debt. If a *capias ad satisfaciendum* be sued out, and a *non est inventus* is returned thereon, the plaintiff may sue out a process against the bail. The second species of execution is against the goods and chattels of the defendant, and is called a writ of *FIERI facias*, which see. A third species of execution is by writ of *LEVARI facias*, which see. This affects a man's goods and the profits of his lands. This writ is now little used, the remedy by *elegit* being much more effectual. This writ of *elegit* is the fourth species of execution. Moreover, upon some prosecutions given by statute, as in the case of recognizances or debts acknowledged on statutes merchant, or statutes staple; (pursuant to the statutes 13 Ed. I. *de Mercatoribus*, and 27 Ed. III. c. 9.) upon forfeiture of these the body, land, and goods

may all be taken at once in execution, to compel the payment of the debt. This process is the fifth species of execution, and is usually called an *extent*, or *extendi facias*, which see. - It is to be observed, that all these writs of execution must be sued out within a year and a day after the judgment is entered, otherwise the court concludes *prima facie*, that the judgment is satisfied and extinct; yet, however, it will grant a writ of *scire facias*, in pursuance of statutes Westm. 2. 13 Edw. I. c. 45. for the defendant to shew cause why the judgment should not be revived, and execution had against him; to which the defendant may plead such matter as he has to allege, in order to shew why process of execution should not be issued: or the plaintiff may still bring an action of debt, founded on this dormant judgment, which was the only method of revival allowed by the common law. (Co. Litt. 290.) Blackst. Comm. B. III.

Sir Edward Coke, in his Reports, makes two sorts of executions; one *final*, another with a *quousque*, as only tending to an end.

*EXECUTION final*, is that which maketh money of the defendant's goods, or extendeth his lands, and delivers them to the plaintiff; which he accepts in satisfaction; and this is the end of the suit, and all that the king's writ commands to be done.

*EXECUTION with a quousque*, is that which only tends to an end; as in the case of a *capias ad satisfaciendum*, &c.

This is not final; but the body of the party is to be taken, to the intent and purpose to satisfy the plaintiff; and his imprisonment is not absolute, but till he doth satisfy; so that the body is but a pledge for the debt. 6 Rep. 87.

*EXECUTION, Tenant by.* See TENANT.

*EXECUTION of criminals*, must be according to judgment; and the king cannot alter a judgment from hanging to beheading, because no execution can be warranted, unless it be pursuant to the judgment. (3 Inst. 52. 211. H. P. C. 252.) But there are ancient precedents wherein men condemned to be hanged for felony, have been beheaded by force of a special warrant from the king. (Bract. 104. Staundf. 13.) And the king may pardon part of the execution in judgment for treason, *viz.* all but beheading. It has been said by sir Edward Coke, and sir Matthew Hale, that the king cannot change the punishment of the law, by altering the hanging or burning into beheading. But others have thought (Fost. 270. F. N. B. 244.), and as judge Blackstone says, more justly, that this prerogative being founded in mercy, and immemorially exercised by the crown, is part of the common law. The court may command execution to be done without any writ; (Finch, L. 478.) though sometimes execution is commanded by writ. (2 Hawk. P. C. 463.) Judgment belongs to the judge; but the execution may be done by the sheriff, or his deputy; and an execution cannot be lawfully made by any but the proper officer, whose warrant for so doing was anciently by precept of the judge under his hand and seal; as it is still practised in the court of the lord high steward, upon the execution of a peer; (2 Hal. P. C. 409.) though in the court of peers in parliament, it is done by writ from the king; and if the sheriff, or other officer alters the execution, or any other executes the offender, or if he is killed without the authority of law, it is felony. (2 Hawk. ib.) The usage now is for the judge to sign the calendar, or list of all the prisoners' names, with their separate judgments in the margin, which is left with the sheriff. As for a capital felony, it is written opposite to the prisoner's name, "let him be hanged by the neck;" formerly,

## EXECUTION.

formerly, in the days of Latin and abbreviation, "sus. per coll." for *suspendatur per collum*. And this is the only warrant which the sheriff has for so material an act, as taking away the life of another. (5 Mod. 22.) Upon this judge Blackstone observes, that it may certainly afford matter of speculation, that in civil causes there should be such a variety of writs of execution to recover a trifling debt, issued in the king's name, and under the seal of the court, without which the sheriff cannot legally stir one step; and yet that the execution of a man, the most important and terrible task of any, should depend upon a marginal note. The sheriff, upon receipt of his warrant, is to do execution within a convenient time, which in the country is also left at large. In London a more solemn and becoming exactness is used, both as to the warrant of execution, and the time of executing thereof; for the recorder, after reporting to the king in person the cases of the several prisoners, and receiving his royal pleasure, that the law must take its course, issues his warrant to the sheriffs, directing them to do execution on the day, and at the place assigned; and in the court of king's bench, if the prisoner be tried at the bar, or brought there by *habeas corpus*, a rule is made for his execution, either specifying the time and place, (State Trials, p. 332. Folt. 43.) or leaving it to the discretion of the sheriff. And, throughout the kingdom, by statute 27 Geo. II. c. 37. it is enacted, that in case of murder, the judge shall in his sentence direct execution to be performed on the next day but one after sentence passed. But otherwise, the time and place of execution are by law no part of the judgment, as was held by the twelve judges. (Mich. 10 Geo. III.) Beccaria has well observed, (On Crimes, &c. ch. 19.) that it is of great importance, that the punishment should follow the crime as early as possible; that the prospect of gratification or advantage, which tempts a man to commit the crime, should instantly awake the attendant idea of punishment. Delay of execution serves only to separate those ideas, and then the execution itself affects the minds of the spectators rather as a terrible sight, than as the necessary consequence of transgression.

In case a man condemned to die, come to life after he is hanged, as the judgment is not executed till he is dead, he ought to be hung up again. (2 Hal. P. C. 412. 2 Hawk. P. C. 463.) For the former hanging was no execution of the sentence; and if a false tenderness were to be indulged in such cases, a multitude of collusions might ensue. The body of a traitor, or felon, is forfeited to the king by the execution. Execution may be avoided by a *reprieve* or a *pardon*, which see respectively.

EXECUTION of decrees, in *Scots Law*, is effected by diligence, either against the person, or against the estate of the debtor. The first step of personal execution is by letters of horning, which pass by warrant of the court of session, on the decrees of magistrates of boroughs, sheriffs, admirals, and commissaries. If the debtor does not obey the will of the letters of horning, within the days of the charge, the charger, after denouncing him rebel, and registering the horning, may apply for letters of caption, which contain a command, not only to messengers, but to magistrates, to apprehend and imprison the debtor. All messengers and magistrates who refuse their assistance in executing the caption, are liable *sulsidiaré* for the debt; and such subsidiary action is supported by the execution of the messenger employed by the creditor, expressing that they were charged to concur, and would not. Letters of caption contain an express warrant to the messenger, in case he cannot get access, to break open all doors, and other lock-fast places. The law secures peers, married women,

and pupils, against personal execution of caption upon civil debts. Such commoners also as are elected to serve in parliament, are secured against personal execution by the privilege of parliament. No caption can be executed against a debtor within the precincts of the king's palace of Holyrood-house; but this privilege of sanctuary afforded no security to criminals, as that did which was by the canon law conferred on churches and religious houses. When the personal presence of a debtor, under caption, is necessary in any of our supreme courts, the judges are empowered to grant him a protection, for such time as may be sufficient for his coming and going, not exceeding a month. Protection from diligence is also granted by the court of session, under the late bankrupt statute, when it is applied for, with concurrence of the trustee, or a certain number of the creditors, as the case may require.

EXECUTION, *military*, is the pillage or plundering of a country by the enemy's army.

Execution also denotes every kind of punishment inflicted on an army by sentence of a court-martial. This is of various kinds; as tying up to three halberts, and receiving a number of lashes with a whip composed of nine cord-lashes, and each lash of nine knots, from the drummer; or running the gantlope through the parade at guard-mounting, drawn up in two lines for that purpose. On this occasion the provost marches through with twigs or switches, and every soldier takes as many as there are criminals to be punished; the criminal then marches through the two lines, and each soldier gives him a hard stroke, the major riding up and down, to see that the men lay on properly. When a soldier is to be punished with death, a detachment of about two hundred men from the regiment to which he belongs forms the parade, and a file of grenadiers shoots the prisoner to death. Different nations have different modes of punishment. The cat with nine tails is designed to punish foot-soldiers; but dragoons and cavalry-men are generally picketed.

EXECUTION, in *Musical Performance*, the action of conveying to the ear, by the assistance of the eye, what has been written in the score. As much music is composed of many parts so interwoven and linked together, that both the time and intonation are very difficult to seize, and of which the spirit depends more on taste than notation of such pieces, nothing is so uncommon as a perfect execution. The reading of the notes exactly is no great merit, the performer must enter into all the ideas of the composer, and feel, and make the hearer feel, the fire or pathos of the expression; but above all he must be possessed of a nice and acute ear, always attentive to the effect of the whole. In French music the leader must be particularly careful to press and relax the time according to the taste of the melody, the power of voice, and the gesticulation of the finger; the other parts must consequently be extremely attentive in following him. "The totality of the opera at Paris, where music had no other measure than the gestures of the singer, must, in my opinion, require an admirable musician indeed to keep all the performers together." N. B. This was written by Rousseau near 40 years ago, and at that time little disputed; but the editors of the late edit. of the Encyc. men of taste and judgment, will, perhaps, say with Moliere, "medicin malgre lui," this may have been so formerly, "mais, nous avons changés tout ca."

"If the French," says St. Evremond, "compose in a bolder style than formerly by their intercourse with the Italians, the Italians in their turn have gained by their commerce with the French, by learning of them a more

## EXECUTION.

agreeable touching, and perfect execution." Letter to the duke of Buckingham.

The reader (says the author of the *Lettre sur la Mus. Fran.*) will, I believe, excuse me if I wave making any remarks on this passage, I shall only observe, that the French think all the world interested about their music; but on the contrary, in three fourths of Italy, Italian musicians are totally ignorant that there exists a music in France different from their own.

A facility of reading and performing a single part is likewise called, if difficult, execution; particularly when rapid passages are played correctly, and without hesitation, at sight.

Execution of this kind depends in an especial manner on two things; the first in having a powerful hand and quick eye; and the second in having read much music, and being able to phrase it at a glance; for while we only look at single notes, we shall hesitate in pronouncing them: a great facility of execution is only acquired by uniting them into meaning, and putting the thing itself in the place of the sign. In this manner the memory of the reader of a book is no less assisted than by his eyes; and what he would read with great difficulty in a foreign language, though written or printed with the same characters as his own.

EXECUTION, in *Painting*, is a technical term signifying the style and manner in which a painter performs his work: in other words, the mechanical part of the art, as far as relates to the handling of the pencil in laying on the colours of a picture.

It is evident from this definition, that without possessing it in some degree, all knowledge of the other branches of the art is totally nugatory; to what purpose would the theory be made perfect, if no practical means of applying it were understood; but besides that degree of execution absolutely requisite to produce any thing in the shape of a picture, it well deserves to be made an object of particular study, as its various modes are productive of much utility in the progress of a picture. A great deal of the character of many objects in painting depends on the manner in which they are wrought, that is, on the peculiarity of the strokes of the pencil; such, for instance, are all skins of beasts; feathers of birds; trees; various kinds of drapery; armour, &c. in producing the effects of which, execution will alone go very far, in spite of bad form and bad colour. There is a charm in it which few perhaps but painters know, and which, unhappily, too many painters feel and value too highly, and desert for it qualities of a much more valuable kind; and are content too often to let their works pass imperfect, even with the knowledge of their imperfections, rather than disturb the beauty of clearness of touch which they may happen to possess.

It is indeed a task of no easy nature fully to obtain this quality, as it requires the utmost precision of judgment so to execute a work of art, that spirit and vigour should be maintained, accompanied with softness and truth. Without which union the display of it is a vice of art instead of an excellence, and damns instead of exalting the work.

Knowledge of the general character of the object about to be represented is the only foundation of a beautiful, decided, and just execution: possessed of that, the artist holds in his hands the master-key of the expression of its qualities, and renders its effect without difficulty. Wanting it he produces his work with heaviness, with bungling, and confusion.

It has been remarked that the countenances of men scarcely differ more than do the characters of their hand-writing, and not far, if at all, short of the variety of either of these,

is that of the manner in which painters have executed their works. Each man in this also has his peculiarity; no two are so exactly alike in the execution of their pictures that an able connoisseur would not distinguish between them, and presently attribute each to its respective author.

This discrimination of hands constitutes almost the tout-ensemble of the knowledge of the host of would-be connoisseurs; and unhappily, too many of them have obtained an influence over the opinions of men well able to teach them in better things appertaining to the arts, if common sense were allowed to rule; and this merely by having pored over the works of painters to endeavour to ascertain the distinguishing characteristics of each one's workmanship: a species of knowledge agreeable and useful to a certain degree, but of easy acquirement, and to which those who have a genuine feeling for the really good and valuable qualities pictures may possess, seldom give sufficient attention to obtain an extended information in it. The works of good artists will force themselves upon our notice, and after sufficiently admiring the general effects of beauty, of sublimity, or character they exhibit; we naturally seek to know by what means or in what manner their various parts are executed, and for the purposes of connoisseurship a satisfactory acquaintance soon takes place on that head. The works of those whose power in art is not sufficient to attract by those better qualities are surely not worthy of that close inspection which is required to become acquainted with their peculiarities of execution. But the trick of the connoisseur dealer is, by some fancied resemblance or some slight reality of resemblance, to pass off an inferior work under the sanction of a great name; while, as we have observed, if common sense were allowed to rule, the name would add no value to the picture, the tinsel would still glare under the gold, and the bauble be soon lost.

This indispensable portion of the art of painting requires early tuition in order to possess a ready power over the hand, so that it shall move freely at the command of the will to effect its desires. The same in fact is the case with regard to the acquirement of free execution in any other art, such as music, writing, &c. For though our muscles appear to act merely on our willing that their office should be performed, and without any particular direction of the power of the mind over the particular muscles which produce the motion, yet, in fact, that immediate influence is applied, although from habit and its extreme rapidity, we are insensible of the communication. This is plain when we require the use of muscles, in a direction we are not constantly in the habit of using them in. For instance, a man not accustomed to ride, or first mounting a horse, finds it necessary to exert all his mental influence to cause those muscles to act which are requisite to maintain his seat on the back of the animal, and the communication of that influence is evidently felt; but when habit has confirmed him in his seat on horse-back, though those same muscles continue to act when he is mounted, he is unconscious of constraining them to do so, the dictates of his will are then so instantaneously excited, that the connection between the exertion of its influence, and its effect is completely unobservable.

It is therefore requisite for men desirous of making considerable progress in the practical part of an art, early in life to apply themselves earnestly to its attainment. The best mode of obtaining it in painting is, by copying the works of those most skilful in their display of it, taking care at the same time to lay in a good store of knowledge of the materials requisite for the art, particularly (if historical painting be the course intended to be pursued) of the human figure, the foldings of draperies, &c. &c., and after some  
time

## EXECUTION.

time spent in making copies of fine works, to paint from nature herself, keeping in view the manner in which the great painters, whose works they have imitated, saw her productions; observing how they disposed of those touches allowed to remain visible, and decided both of light and of dark; also how they characterized by their execution of the different parts; for, in a well executed work no touches are allowed to remain that are not necessary in some measure to determine the character of the object; the rest are all blended or softened together, and serve as a base to receive those finishing touches (as they are called) which are the decided features of the style of the master, (see *STYLE*, in *Painting*;) the spring of energy and vigour in the work, and without which it would appear tame and insipid.

A picture, wherein the colours and forms are blended all over, is sure to appear either solid like a stone, or have the texture of dough, of something soft and spiritless. On the contrary, where no softening takes place, and every touch remains visible, confusion inevitably reigns, with the character of tinsel, and a fluttering want of solidity.

While the student is endeavouring to acquire facility of handling his pencil, or of execution, he must take care not to be led away by its fascination, but to remember that it is only the means of presenting to the world, in an agreeable shape, other more dignified, and more valuable qualities in art, which lie deeper than the surface; and without which this is worse than an empty nothing. 'Tis the bane of many an ingenious youth who, happening to possess it early, and outshining his companions in years, satisfies himself that he has made a large advance in his art, when in fact he has obtained only a means of doing something, which more important part, his vanity leads him to forget to make the studies requisite to enable him to perform, *viz.* to acquaint himself thoroughly with the nature of bodies, and the happiest and best modes of combining them in forms and colours: and as he advances in life he is mortified to find himself surpassed by those he had regarded with contempt, but whose more steady and better directed minds have pursued attentively more valuable objects of study, and the more useful principles of their art, and now soar to a height which leaves his weaker talent far beneath.

It must, however, be remarked, that a good execution is a highly valuable quality in a picture, which being wrought with judgment, with spirit, and ease, acquires thereby an additional relish to the enjoyments its better properties dispense, and raises the artist in our estimation.

Of all those who have exhibited this talent with success, Giacomo Robusti, called Il Tintoretto, stands foremost for vigour, as has been noticed under the word *ENERGY*, in *Painting*. He has no competitor in the freedom, the boldness, and the finish of style in which his best works are executed.

Of this his picture of St. Mark descending from heaven to rescue a Christian slave condemned to torture among the Turks, originally painted for the Scudo di San Marco at Venice, but now among the spoils adorning the Louvre at Paris, is a most decided and astonishing proof. This picture is an immense work containing twenty figures or more, those in front larger than life, yet it is wrought all over with the rapidity and ease generally characteristic of small pictures, or a sketch within the compass of the hand to perform at once; and at the same time it has all the effect of rotundity of finish the most laboured works possess. In the midst of the fine pictures which surround it, it stands quite alone in its vigour of effect and splendour of colour; even a work of Rubens, who is extremely skilful in this as well as in all other branches of the art; even his, appeared compa-

ratively clumsy in its execution, though one of his finest productions, the opening of the Temple of James, or, as it is usually called, the Peace and War. Titian, from his sense and truth in the St. Peter martyr, best withstands the power of Tintoretto. The comparison of these two works may be said to be somewhat similar to that of a man of wit with a man of sense: the former shines for a moment by the brilliancy and gaiety of his genius, but when the latter is attentively heard, and his observations considered, his greater value becomes apparent.

Titian perhaps on the whole is the best model to follow for execution: he does not, like Tintoretto, leave his heads without a character in the heat of workmanship, though they are not always of the best; they are not wrought too minutely: the lights and darks are freely placed, his pencil is full and rich, and each part is made out to its full relief, and his finishing touches are laid on with the nicest discrimination of truth in direction of light and hue of colour; nothing can exceed the delicacy and skill his draperies are wrought with as to character; and though not so strong as Tintoretto's, they have sufficient force, and are far more justly disposed and characterized. After Titian in imitating him are, Velasquez and Vandyke for excellence in their execution. Of the former, a Spanish painter, there are but few works in this country, but what there are, fully justify the remark. The latter in his very finest works equals his great predecessor in this respect, many of whose pictures he carefully copied. His touch is exceedingly delicate, and his understanding of his subject enabled him to place it with the greatest justness and propriety. There is rarely seen in his works a confusion in effect or relief, and his power in his earlier productions seems to have increased with his canvas; the large picture at Wilton of the Pembroke family is wrought in a style so broad and masterly, that it appears to have been as easily managed as any of his smaller pictures; and he knew how to give with the greatest ease the just character of every object he attempted to represent. Gout and consequent weakness effected a change in his execution so great, that his hand is hardly cognizable in some of his latter works by those who have only seen his former ones. When he was in Italy, his manner was that of Titian, with somewhat of Tintoretto; from this bravura style, as it may be termed, he fell afterwards to one more tame and spiritless; softened, and rounded up, with few of those vigorous touches, and with less brilliancy of effect. Instances of both these, and also intermediate degrees, are at the earl of Egremont's at Petworth. Of the first are whole length portraits of sir Robert and lady Shirley, which he painted when he was very young at Venice; of the others, are portraits of several branches of the Pony family, who once possessed that noble mansion. Vandyck certainly surpassed his master Rubens in beauty of execution, but was more than equally surpassed by him in vigour and variety of imagination; yet the execution of Rubens was extremely powerful, but apt to become slovenly, and he is not, generally speaking, a good model to be followed on that head.

For those who are intent upon yielding the soft, the delicate, and gentle impressions produced by highly laboured works without minuteness, Correggio is the exemplar of the whole class of that style of painters. In one particular he, and our own sir Joshua, in some of their works, stand unrivalled in execution. Other painters have given a beautiful surface, which, at a proper distance, deceives the eye, and presents the full appearance of flesh: these two have, we may almost say, made flesh itself; the closest inspection merely confirms the delusion, and the observer fancies he could indent his finger in the surface, and expect it to spring again like nature;

such

Such is the fullness of the texture of the colour wrought with the many varying hues of nature. Guido Rheni follows in this class of the pleasing style. His pictures of the lighter kind are exceedingly grateful to the eye, from the intelligence and ease with which his pencil appears to have been conducted through all the various parts. Annibal Carracci, in a more bold manner, is also a master of great power in the execution part of the art; but he often appears to have laboured to express his thoughts; his works, however, possess great beauties of this nature.

In works of a different and smaller class from those produced by the masters whose names we have mentioned, almost the whole of the Dutch and Flemish schools are wonderfully skilful in their execution, particularly Rembrandt, Teniers, Janssen, Metz, Netscher, &c. and still more minute Gerard Dow, and Meins. In landscape, Cuyp, Berghem, Both, Ruysdael, and Hobbima, are all well worthy of the utmost attention in this respect; and many others, too numerous to be mentioned here, both of these and the Italian school, will greatly assist the student who attentively examines their productions to form his judgment, on those points wherein lie the greatest beauties of this necessary branch of the art of painting. But as a good execution consists in a free and ready hand, marking with fullness of precision and truth the characters of the objects represented; nothing but an intimate knowledge of nature will ever enable him to apply his observations on works of art to any beneficial purpose in completing the productions of his own imagination.

**EXECUTIONE facienda**, in *Law*, a writ commanding execution of a judgment.

**EXECUTIONE facienda in withernamium**, lies for taking the cattle of one who had formerly conveyed out of the county the cattle of another, so that the sheriff cannot replevy them.

**EXECUTIONE Judicii**, a writ directed to the judge of an inferior court, to do execution upon a judgment therein, or to return some reasonable cause wherefore he delays the execution. F. N. B. 20.

If execution be not done on the first writ, an *alias* shall issue, and a *pluries*, with this clause, *vel causam nobis significes quare, &c.* And if, upon this writ, execution be not done, or some reasonable cause returned why it is delayed, the party shall have an attachment against him who ought to have done the execution, returnable in B. R. or C. B. New. Nat. Br. 43.

**EXECUTIVE POWER**, *Supreme*, is by the constitution of these kingdoms lodged in a single person, the king or queen for the time being. See **CROWN** and **KING**.

**EXECUTOR**, a person nominated by a testator, to take care to see his will and testament executed or performed, and his effects disposed of according to the tenor of the will.

The testaments made in Latin, in the fourteenth century, call executors *provisores testamentarii*.

All persons are capable of being executors that are capable of making wills, and others besides, as feme-coverts and infants, and infants unborn; (West. Symb. p. 1. § 635.) but no infant can act as executor till he is seventeen years of age. This appointment of an executor, either by express words, or by such as strongly imply the same, is essential to the making of a will; (West. c. 1. Plowd. 281.) but if the testator names no executors, or names incapable persons, or if the executors that are named refuse to act, the ordinary must grant letters of administration. See **ADMINISTRATOR**.

A person appointed to be executor is not compellable to

execute the will; he may refuse the charge, before he has administered as executor, or performed such acts, as paying debts due by the testator, or receiving debts due to him, or giving acquittances for the same; but if he meddles with the goods of the testator, as executor, his subsequent refusal is void, and he shall be charged as executor. A person to whom a legacy is left may be compelled either to stand the executorship, or to resign his legacy. The refusal of executorship must be entered and recorded in court. If several executors are named in a will, and some of them refuse, and others prove the will, they who refuse may afterwards administer and act; and they must be joined in all suits, where the co-executors are plaintiffs; but not where they are defendants; because the plaintiff in the action is not bound by law to take notice of any besides those who have proved the will. Such joint-executors, though they are accounted in law but as one person, shall not be charged by the acts of their companions, any further than for effects *actually* come to their hands. (Moor. 620. Cro. Eliz. 318. 2 Leon. 209.) But if two or more executors join in a receipt (in writing) and one of them only actually receives the money, each is liable for the whole, as to creditors at law, but not as to legatees or next of kin. (1 Salk. 318.) If joint-executors, by agreement among themselves, agree that each shall intermeddle with a certain part of the testator's estate, yet each shall be chargeable for the whole (to creditors) by agreeing to the other's receipts. Hard. 314.

The interest, vested in the executor by the will of the deceased, may be continued and kept alive by the will of the same executor, so that the executor of A.'s executor is to all intents and purposes the executor and representative of A. himself. (Stat. 25 Edw. III. st. 5. c. 5. 1 Leon. 275.) But the executor of A.'s administrator, or the administrator of A.'s executor, is not the representative of A. For the power of an executor is founded upon the special confidence and actual appointment of the deceased; and such executor is therefore allowed to transmit that power to another, in whom he has equal confidence; but the administrator of A. is merely the officer of the ordinary, prescribed to him by act of parliament, in whom the deceased has reposed no trust at all; and therefore, on the death of that officer, it results back to the ordinary to appoint another.

As to the office or duty of an executor, it is to be observed that he may do many things before he proves the will, which an administrator cannot do; because the former derives his power from the will, and not from the probate or appointment of the ordinary, as the latter does. (Comyns. 151. Wentw. ch. 3.) He may maintain actions of trespass, replevin, or detinue; release an action, assent to a legacy, be sued, alien, or otherwise intermeddle with the goods of the testator: by administering, the executor is entitled to receive all debts due to the testator, and all payments made to him are good, though he should die, and never prove the will; but he cannot maintain a suit or action of debt, or the like, before he has proved the will. The ordinary, &c. may cite the executor, either to prove the will, or refuse the office; and he may sequester the goods of the deceased, till the executor has proved it; and if he does not appear on the process, the ordinary may excommunicate him. On the other hand, the ordinary is compellable by mandamus to proceed to probate, when the will is not controverted. The executor must bury the deceased in a manner suitable to the estate he leaves behind him; necessary funeral expences are allowed, previous to all other debts and charges; but if he be extravagant, he is chargeable with devastation, or waste of the substance of the deceased, which shall be only prejudicial to himself,

and not to the creditors or legatees of the deceased. (Salk. 196. Godolph. p. 2. c. 26. § 2.) He is then to make an inventory of all the goods and chattels, whether in possession or action of the deceased, which he is to deliver in to the ordinary upon oath, if lawfully required. He is then to collect all the goods and chattels so inventoried; for which purpose the law confers on him ample powers, as the representative of the deceased; (Co. Litt. 209.) and having the same property in his goods as the principal had when living, and the same remedies to recover them; and if there be two or more executors, a sale or release by one of them shall be good against all the rest. (Dyer. 23.) The executor must in the next place pay the debts of the deceased, in the order of their priority. See DEBT, and DEBTEE Executor.

Among debts of equal degree, the executor (and also the administrator) is allowed to pay himself first, by retaining in his hands so much as his debt amounts to. (10 Mod. 496.) If a creditor constitutes his debtor his executor, this is a release or discharge of the debt, whether the executor acts or not, (Plowd. 184. Salk. 299.) provided there be assets sufficient to pay the testator's debts.

If no suit has commenced against him, the executor may pay any one creditor in equal degree his whole debt, though he has nothing left for the rest; for, without a suit commenced, the executor has no legal notice of the debt. After the debts, the executor is to pay the legacies, which he is to pay as far as his assets will extend; but he may not give himself the preference herein, as in the case of debts. In case of a deficiency of assets, all the general legacies must abate proportionably, in order to pay the debts; but a specific legacy, as of a piece of plate, horse, &c. is not to abate at all, unless there be not sufficient without it. (2 Vern. 111.) If the legatees have been paid their legacies, and debts come in more than enough to exhaust the residuum, they are afterwards bound to refund a rateable part. (Ibid. 205.) See LEGACY, and DONATION *Causa Mortis*.

When all the debts and legacies are discharged, the surplus or residuum must be paid to the residuary legatee, if any be appointed by the will; if there be none, it was formerly understood to belong to the executor; (Perkins, 525.) but it seems to be now the general opinion, that, if there be an express legacy given to an executor, and no devise of the surplus, such surplus shall not go to the executor; but be disposed to the next of kin, according to the statute of distributions; the executor standing on the same footing as an administrator. (Prec. Chanc. 323. 1 P. Wms. 7. 544. 2 P. Wms. 338. 3 P. Wms. 43. 194. Stra. 559.) See INTESTATE.

Where no express legacy is given to the executor, the surplus shall go to the executor, and not otherwise disposed of by will. When there are several executors, and some of them are dead, the legatary must sue the surviving executors, and not the executors or administrators of those that are dead. And if all the executors are dead, he must sue the executors or administrators of those that died last, and not those of the rest.

By the French law, an executor should be seised of all the moveables of the deceased during one year; at the end whereof he is to account for them. To the validity of a testament, it is not necessary there be an executor nominated therein.

EXECUTOR *de son tort*, or of his own wrong, is he who takes on him the office of an executor by intrusion, not being constituted thereto by the testator or deceased, nor authorized by the ordinary to administer.

If an executor in his own wrong takes upon himself the

office of an executor, without lawful authority, he is chargeable to the rightful executor, and to all the creditors of the testator, and likewise to the legatees, so far as the goods amounted to, which he wrongfully possessed; and such an executor is made by any act of acquisition, transferring, or possessing himself of any of the estate or goods of the deceased; but not by acts of necessity, piety, or charity. (2 Nelson Abr. 793.) Such an executor cannot bring an action in right of the deceased; but actions may be brought against him; neither can he retain for his own debt or legacy. In case of his death, his executors or administrators are liable to the suit of the lawful executor, creditors, and legatees, by 30 Car. II. cap. 7.

EXECUTOR, *Debtee*. See DEBTEE.

EXECUTORY, that which has, or carries with it a sufficient authority for being executed.

EXECUTORY *contract*. See CONTRACT.

EXECUTORY *devise of lands*, is such a disposition of them by will that thereby no estate vests at the death of the deviser, but only on some future contingency.

It differs from a remainder (which see) in three very material points: 1. That it needs not any particular estate to support it. 2. That by it a fee-simple, or other less estate, may be limited after a fee-simple. 3. That by this means a remainder may be limited of a chattel interest, after a particular estate for life created in the same. The first case happens, when a man devises a future estate to arise upon a contingency; and, till that contingency happens, does not dispose of the fee simple, but leaves it to descend to his heir at law. As if one devises land to a feme-sole and her heirs upon her day of marriage; here is in effect a contingent remainder without any particular estate to support it; a freehold commencing *in futuro*. This limitation, though it would be void in a deed, yet is good in a will, by way of executory devise. (1 Sid. 153.) For, since by a devise a freehold may pass without corporal tradition or livery of seisin, it may therefore commence *in futuro*; because the principal reason why it cannot commence *in futuro* in other cases is the necessity of actual seisin, which always operates *in presenti*. And since it may thus commence *in futuro*, there is no need of a particular estate to support it; the only use of which is to make the remainder, by its unity with the particular estate, a present interest. And hence it follows, that such an executory devise, not being a present interest, cannot be barred by a recovery, suffered before it commences. (Cro. Jac. 593.) The second case happens where a deviser devises his whole estate in fee, but limits a remainder thereon to commence on a future contingency. As if a man devises land to A. and his heirs; but if he die before the age of 21, then to B. and his heirs; this remainder, though void in a deed, is good by way of executory devise. (2 Mod. 289.) But in both these species of executory devises, the contingencies ought to be such as may happen within a reasonable time; as within one or more life or lives in being, or within a moderate term of years; for courts of justice will not indulge even wills, so as to create a perpetuity, which the law abhors. (12 Mod. 287. 1 Vern; 104.) Thirdly, by executory devise a term of years may be given to one man for his life, and afterwards limited over in remainder to another, which could not be done by deed; for by law the first grant of it, to a man for life, was a total disposition of the whole term; a life estate being esteemed of a higher and larger nature than any term of years. (8 Rep. 95.) On this subject, see Blackst. Comm. vol. ii. p. 176, 8vo.

EXECUTORY *estate*. See ESTATE.

EXECUTORY *fine*. See FINE.

EXEDENS HERPES. See HERPES.

EXEDRÆ, Ἐξεδραί, among the *Ancients*, were places wherein the philosophers, sophists, rhetors, &c. used to hold their conferences and disputes.

M. Perrault is of opinion, the *exedræ* were a sort of little academies, where the men of learning met together. See ACADEMY.

Budæus rather thinks, that what the ancients called *exedræ*, might answer to what we call chapters in the cloisters of monks, or collegiate churches.

EXEGESIS, Ἐξήγησις, a term sometimes used by the learned, to signify *explication*.

Several interpreters of the Bible are of opinion, that in the passages of Scripture, where we meet with Abba Pater, two words, the first Syriac, and the second Greek or Latin, but both signifying the same thing; the second is only an *exegesis*, or explanation of the first.

EXEGESIS is also used for an entire discourse by way of explication or comment on any thing.

EXEGESIS *numerosa*, or *linealis*, signifies the numeral, or lineal solution, or extraction of roots, out of affected equations, first invented by Vieta. Ozanam calls it *la rhetique*. See EXTRACTION of roots.

EXEGETES, formed of ἔξηγηταί, *I explain*, among the Athenians, persons learned in the laws, whom the judges used to consult in capital causes.

EXEGETICA, in *Algebra*, the art of finding, either in numbers or lines, the roots of the equation of a problem, according as the problem is either numerical or geometrical. See ROOT and EQUATION.

EXELCOSIS, from ἕλκος, *an ulcer*, in *Surgery*, an incipient ulceration, or an excoriation, which is just beginning to suppurate.

EXEMPLAR, a model or original to be imitated or copied.

EXEMPLAR also denotes the idea or image conceived or formed in the mind of the artist, whereby he conducts his work. Such is the idea of Cæsar, which a painter has in his mind when he goes to make a picture of Cæsar. The exemplar is ordinarily numbered among the causes. See CAUSE.

EXEMPLIFICATION of *Letters Patent*, denotes an exemplar, or copy of letters patent, made from the inrolment thereof, and sealed with the great seal of England.

Such exemplifications are as effectual to be shewed, or pleaded, as the letters patent themselves.

EXEMPLIFICATIONE, in *Law*, is a writ granted for exemplification of an original record. Reg. Orig. 290.

EXEMPTION, a privilege, or dispensation, whereby a person is excepted out of some general rule.

Exemption is particularly applied to churches, chapels, and monasteries, which have a privilege given them by the popes, or princes, whereby they are exempted from the jurisdiction of the bishop or ordinary.

The council of Constance revoked all exemptions, to restore to the general-law, weakened and diminished by a relaxation of several ages, its ancient force and vigour, and make it every where obtain in all its latitude.

The council of Trent prohibited, and declared them null for the future; confirming only such as were well founded on legal concessions from the holy see.

EXEMPTION, in *Law*, denotes a privilege to be free from service or appearance; thus, knights, clergymen, &c. are exempted from appearing at the county courts by statute, and peers from serving on inquests. (6 Rep. 23.) Persons seventy years of age, apothecaries, &c. are also exempted

by law from serving on juries, and justices of peace, attornies, &c. from parish offices. 2 Inst. 247.

EXERCISE, a repetition of any operation, for the strengthening or retaining of a habit.

EXERCISE, or bodily motion, constitutes, in the language of the older physicians, one of the six *non-naturals*, and has been justly considered, from the earliest times, as an important measure in the preservation of health, as well as in the cure of several diseases.

The value of corporeal exercises in the estimation of the ancient physicians, from Hippocrates downwards, is manifest from their writings, in which the various kinds of exercise, as well as the degrees and times in which they are useful, are particularly discussed. Esculapius himself is said by Galen to have recommended riding on horseback, and other exercises, as the means of benefiting invalids. But Herodicus, a Thracian, seems to have been the first who paid serious attention to exercise, as a remedy for diseases. He was master of one of the academies, called *Gymnasia*, in which the military and athletic exercises were taught; and having remarked that his pupils usually enjoyed high health, he turned his attention to the regulation of the gymnastic exercises, with a view to attain or preserve good health; thus adding the *medical gymnastic art*, to the two others just mentioned. (See GYMNASTIC, and HERODICUS.) This master of the gymnasium, however, went to work empirically, and is accused by Hippocrates of doing considerable mischief, in attempting to cure febrile diseases by his exercises. (De Morb. Epidem. lib. vi.) Hippocrates and his commentator, Galen, have left many observations relative to the different exercises, and their particular effects in the alleviation of particular diseases. Friction, especially by means of the *strigil*, or flesh brush, is much inculcated; on which subject Galen has composed his second book, "De Sanitate Tuenda." The various modes of wrestling, the exercises of the *corycus*, or hanging ball, &c. are commented on by Hippocrates in lib. ii. De Diæta: and Galen wrote a little treatise *de parva pila*, (the little ball,) which he recommends as an exercise that influences both the body and the mind at the same time. In his discourse to Thrasibulus he discusses the question, whether the preservation of the health properly belongs to medicine, or to the gymnastic art: he inveighs against the athletic and other violent practices of the gymnasium, but approves of the more moderate exercises, which he considers as subservient to the purposes, and consequently a part of the art of the physician. Antyllus, and other Greek writers, have treated of the various exercises in the same light, as is evinced by the collections of Oribasius. (See Collect. Med. lib. vi.) The Romans even exceeded the Greeks in their attention to the medical gymnastics. Asclepiades, in the time of Pompey, as Pliny informs us, considered the different modes of exercise, *viz.* friction, walking, and gestation, as the chief auxiliaries of the physician, especially when combined with the proper regulation of diet; and by the employment of these exercises, the institution of baths, the invention of hanging beds, *lecti pensiles*, and other means of making physic agreeable, he is said to have acquired the general applause of all mankind: "universum prope humanum genus circumegit in, &c." (Plin. Nat. Hist. lib. xxvi. cap. 3.) Many eminent examples of the benefits of exercise among the Romans are on record. Suetonius states that Germanicus was cured of a sort of atrophy of the lower extremities, (*crurum gracilitas*) by riding. And Cicero himself, when reduced to a state of infirmity, which rendered it necessary for him to desist from pleading, recovered his health by travelling, and by excessive diligence in the use

## EXERCISE.

of friction. (Plutarch.) Friction was an exercise, indeed, reduced to a regular system among the ordinary habits of the Romans, and was preferred to a great extent by their physicians. See FRICTION.

That exercise, especially in the open air, is highly beneficial to the constitution, is a truth which universal experience has established. It is scarcely necessary, therefore, to appeal to the arguments of physiology to corroborate the proposition. It may be sufficient to state, that the immediate result of bodily exertion is an acceleration of the circulation of the blood; a quicker and stronger contraction of the heart, by which the blood is pushed more effectually to every part of the system, and especially through the small and extreme branches of the vessels. Hence a glow is produced on the surface, and the complexion assumes a redder hue, from the distention of the capillary vessels with blood; and the exhalent arteries begin to pour out the thinner portions of the fluids in perspiration. In the same manner, the extreme arteries of all the other parts of the body are distended, and excited to greater action; whence all the organs of secretion, which are principally made up of convolutions of the extreme arteries, are necessarily stimulated to an active performance of their several functions. The vessels of the stomach pour out the gastric liquors more abundantly, and the work of digestion is more perfectly and actively completed; the appetite for a new supply of aliment quickly returns, and the stomach is prepared for repeating the digestive process, by the increased supply of the digestive liquor. The liver and the pancreas, in like manner, elaborate their respective fluids, the bile and pancreatic juice, more copiously, and thus contribute an increased aid to the operations of the alimentary canal. The lungs, in the mean time, being called upon for an augmented supply of the vivifying principle derived from the oxygen of the atmosphere, by the increased circulation of the blood through them, respiration is increased in proportion to the quantity of venous blood which they receive. Thus, notwithstanding the greater rapidity with which the blood is carried to the secreting organs, it is rendered adequate to the secretion of the healthy fluids peculiar to each, by the increased operation of the lungs; as well as to the support of the greater muscular action, in which the exercise consists.

It must be obvious, then, that this general activity of the whole system, this free circulation through the most minute ramifications of the vessels, and through the glands and organs which they compose, and this prompt separation of the excrementitious and other parts of the blood, by the secretions, cannot but contribute to the general health of the body. It is not less obvious that it contributes to the evolution and growth of the different parts of the body; whether we consider the great influx of the blood, from which all growth is derived; or observe the fact, that those muscles and limbs, which are most actively exercised, invariably acquire superior bulk, as well as superior strength. The muscles of the arms in blacksmiths, and those of the loins in porters, and all others employed in raising or carrying great weights, invariably acquire a disproportionate size; and, on the contrary, those muscles which are little employed are apt to shrink, and to be comparatively enfeebled, as in the legs of tailors. The effect of exercise in giving strength and rigidity of fibre to the muscular or fleshy part of animals is well known, and daily exemplified in the difference of texture in the wings and legs of birds which we use as food. In the common fowls, which seldom use the wing, and constantly employ the legs in walking, the hardness of the flesh of the latter, and tenderness of that of the former, are notorious. From this influence of exercise in con-

tributing to the growth and strength of the animal body, we may obviously trace the final cause of that instinctive disposition to activity and motion, which the young of all animals possess.

Regular exercise, not too violent in degree, nor continued too long, so as to induce excessive fatigue, is therefore to be considered as the most important preventive of diseases. It is not easy to lay down rules by which it should be regulated; since the constitution, age, strength and habits must modify its effects in different individuals. A sudden transition from a state of rest to violent exertion is injurious to the invalid, especially after a full meal, or if continued until a profuse perspiration, or great lassitude takes place; for this over-exertion necessarily leads to a languor and imperfect performance of all the vital actions, every organ partaking of the general fatigue. The various kinds of exercise may be considered under two classes, the active and the passive; the former being the result of our own muscular activity, such as walking, dancing, running, swimming, fencing, the military exercise, and different athletic games; the latter the result of communicated motion, as riding in a carriage, sailing, swinging, friction, &c.; riding on horseback, or driving a carriage, partakes in some measure of both the active and passive exercises.

Walking, which seems to be the most natural exercise, is capable of producing all the effects above detailed, if adapted in degree and duration to the various circumstances. Hence the most obstinate cases of hypochondriacal disorders, of indigestion, and other stomach complaints, have been frequently removed by perseverance in walking, especially in the open air of the country. But when the exercise of walking is adopted with a view to banish the complaints just mentioned, which a sedentary life is apt to induce, it is most effectual when regularly and strenuously pursued. That degree of walking, which, when resorted to occasionally, or with considerable intermissions, produces great fatigue and languor, and therefore is rather prejudicial than advantageous, would, if daily continued, soon cease to fatigue, and would then contribute greatly to restore the healthy state of the functions. It must be recollected that the animal vigour is consumed, or, to use the language of Brown, the excitability is exhausted, by the mental functions as well as by muscular exertion; therefore, to carry with us, in our walks in search of health, the brooding anxieties and cares of our professions,—to attempt to combine study with such exercise by reading, or by serious reasoning in conversation, is to thwart the good effects of the plan. We may observe that, so incompatible is deep thought with muscular exertion, that most people stop in the midst of their activity, when their arguments require great reflection. Serenity of mind, and a relaxation from the serious occupations of life, are therefore necessary, when walking is resorted to as a remedy.

Of the more violent species of active exercise, which can only be resorted to as a preservative from disease, by those who are in a state of good health, it is unnecessary to speak.

The modes of exercise which are particularly useful in the cure of diseases, or in the restoration of the health of convalescents, are the different species of gestation, especially riding in carriages, or on horseback, and sailing.

The motion of a ship produces the most gentle exercise, and is therefore adapted even to the relief of very infirm conditions of the body, and it has been employed from early times in the cure of consumption. The Romans, in the time of Pliny, used to send their consumptive patients to Egypt; not, as that author takes care to inform us, on

## EXERCISE.

account of any peculiarity of that country, but in consequence of the length of the voyage. *Annaeus Gallio*, who had been consul, was cured of a consumption by such a voyage. (*Nat. Hist. lib. xxxi. cap. 6.*) *Celsus* seems to have considered sailing, when resorted to early, as the principal remedy for consumption: "opus est, si vires patiuntur, longa navigatione," he says; and where the strength is not equal to it, he recommends short voyages, or the use of a litter, or other means of gentle gestation. (*De Medicina, lib. iii. cap. 22.*) The advantages of a sea voyage, especially to a warmer climate, are well known to modern physicians; and instances of the success of such a voyage to *Madeira*, *Lisbon*, &c. when undertaken in the incipient stage of consumption, as *Celsus* recommends it, are very numerous. This, however, like all other remedies for consumption, is too often resorted to when the disease has already advanced too far to admit of any effectual relief. See CONSUMPTION.

The exercise of gestation by means of a carriage, and the more active exercise of riding on horseback, being more easily obtained, are of more importance in our consideration of the subject. Horseback exercise was not much adopted by the ancients, with a view to the cure of diseases; partly because that valuable animal was less used by the Greeks and Romans, and partly because their mode of riding, without stirrups, was incompatible with the weakness of invalids. (See *Fuller, Medicina Gymnastica, p. 231.*) Hence we may understand the observation of *Antyllus*, that "riding is of little use to those who are sickly, because a slow pace is productive only of lassitude, especially in the loins;" he admits, however, that "a quick pace of the horse, although it occasions a troublesome shaking of the whole body, is nevertheless somewhat beneficial, and strengthens the system, especially the stomach and the organs of sense, more than all other exercises." (*Oribasius, loc. cit. lib. vi. cap. 24. de Equitatione.*) The great advantages of riding in the prevention and cure of many diseases are insisted upon in the strongest terms by *Sydenham*, who, indeed, appears, in several parts of his writings, to have considered it as a remedy of inestimable value, provided it be persevered in with constancy, in the manner which we have inculcated in respect to walking. Speaking of the mode of cure in chronic diseases, that sagacious physician observes, "nothing, among all the expedients which have hitherto come to my knowledge, so effectually supports the spirits and strength, as long and constant riding on horseback." (*Diff. Epistolaris.*) Again in his *Treatise on the Gout*, and particularly respecting the prevention of the paroxysms by exercise, he says, "riding on horseback is far preferable to all other exercises for this purpose; in truth I have frequently considered, that if any person were acquainted with a medicine, which he chose to keep secret, of equal efficacy in this, and in the greater number of chronic diseases, with a constant and persevering exercise on horseback, he would speedily accumulate the most ample wealth." And to express his full conviction of the value of this exercise in consumptive complaints, he uses these strong terms: "in short, however fatal consumption is deemed to be, and actually is, since it destroys two thirds of those who die of chronic diseases, yet I solemnly affirm, that neither is mercury a more effectual remedy for the lues venerea, nor Peruvian bark for agues, than is the exercise just commended for consumption, provided that the patient be always careful to sleep in dry linen, and that his journey be sufficiently long." The truth of this great encomium is indeed questioned by modern practitioners in general, however weighty the authority of *Sydenham* may be. But there are many cases on record,

which seem to justify this observation. Witness the case of the late *Dr. Currie*, of *Liverpool*, as related by himself, in the *Zoonomia* of *Darwin*. (*Vol. ii. class. ii. Ord. i. 6.*) In this case, the patient had an hereditary predisposition to consumption, and was restored by travelling from a state of debility, in which the erect posture could scarcely be borne without fainting, to good health; having begun with the exercise of a carriage, and afterwards ridden on horseback, as his strength augmented. *Sydenham* has related several examples of the value of this exercise, and others may be found detailed by *Fuller*, &c. We cannot therefore doubt, that in many instances, in which it has seemed to be destitute of the efficacy ascribed to it by *Sydenham*, the failure must be attributed to the imperfect or too late use of the remedy. "I must here repeat," says *Fuller*, quaintly, "that when I speak of riding, I understand the habit of riding, the want of which distinction has made it ineffectual to many a man. He that in this distemper (consumption) above all others rides for his health, must be like a Tartar, in a manner always on horseback; and then from a weak condition he may come to the strength of a Tartar." (*Medicin. Gymnast. p. 106.*) We have dilated upon this topic, from a conviction that many chronic diseases, which are included under the epithets of bilious and nervous, as well as many morbid conditions of the viscera, for which drugs, and even the waters of *Bristol*, *Bath*, and *Cheltenham*, are ineffectually swallowed, might be removed by a steady and unremitting exercise, in a carriage, or still more certainly on horseback.

It is unnecessary to enter into a particular enumeration and discussion of every possible form of exercise, the principle being the same with respect to all. A late intelligent writer has laid down some useful practical precepts on these topics, mixed with a good deal of trifling observation, and absurd hypothesis. (See *Willich's Lectures on Diet and Regimen, chap. 7.*) The following remarks on the injuries occasioned by want of exercise are from that popular writer.

"We are now to consider the consequences arising from want of exercise. This, indeed, is still more debilitating than too violent motion. The solid parts of the human frame are relaxed by it; the circulation of the fluids is retarded; they gradually stagnate in the smaller capillary vessels; the secretions are diminished; and abundance of moisture or fat is generated, which renders the body, as well as the mind, more indolent and lethargic, relaxation of the muscles, obstructions of the intestines, hemorrhoids, apoplectic fits, various species of dropsy, and at length a premature death, are the sad consequences. Men of letters are the most unhealthy of all human beings, because their bodies have scarcely any other exercise but the imperceptible motion of the arms. Want of appetite, flatulency, anxiety, at one time obstructions, at another diarrhœa, and the most diversified nervous symptoms are their attendants. Sleep is beyond their reach; a thousand tormenting inconveniences, hypochondriasis, and at length a complete state of melancholy, is too frequently their lot. Temperance alone will not remedy all these evils; for, since we cannot remain vigorous and healthy for two days together, with the same mass of blood, a new access of the newest and most subtle parts of our fluids must daily support the nervous system, in order to preserve its regular functions. If this be not continually restored, weakness and relaxation of body and mind are the inevitable consequences; with this difference only, that in a state of debility from too much bodily exercise, the thick and coarse particles of the fluids are carried into circulation with the others, and the next meal or the first sleep after it, soon

soon supplies the deficiency in mental labour; on the contrary, digestion is interrupted, the crude and viscid parts of food remain unassimilated, and the body is prevented from receiving proper nourishment. In like manner sedentary mechanics and artificers are affected, particularly shoe makers, tailors, and weavers. They experience maladies similar to those to which men of letters are subject; and it has been frequently observed, that they are very liable to diseases of the mind, and especially to religious fanaticism."

**EXERCISE, Field, in Military Affairs,** relates to the evolutions performed by companies, regiments, or greater bodies of troops, when learning, or practising, those movements necessary to be correctly understood by persons of all ranks in the military profession. See **EVOLUTIONS** and **TACTICS**.

**EXERCISE, Gun,** relates to the several arrangements, and motions, made for serving either heavy or light artillery, under every circumstance common to military operations. See **GUN-Exercise**.

**EXERCISE, Manual,** teaches the several motions of the firelock, whereby all act as it were in unison, and perform their duties when drawn up for display, or for service, in an uniform and appropriate manner. See **MANUAL-Exercise**.

**EXERCISE, Sword,** refers to the several positions of the sword, adapted either for attack, defence, or compliment. See **SWORD-Exercise**.

**EXERCISE, in a Naval Sense,** is the preparatory practice of managing the artillery and small arms, in order to make the ships' crew perfectly skilled therein; so as to direct its execution successfully in time of battle. The words of command introduced, during the late war, for the exercise of the great guns, are the following: "Silence: cast loose your guns; level your guns; take out your tompions; run out your guns; prime; point your guns; fire; sponge your guns; load with cartridge; shot your guns; put in your tompions; house your guns; and secure your guns. Falconer's Marine Dict. art. *Exercise*."

Exercise may also denote the execution of the movements, which the different orders and dispositions of fleets occasionally require, and which the several ships are required to perform, by means of signals.

**EXERCISES,** in the plural, are particularly understood of what is taught young gentlemen in the academies, or riding-schools, &c. As riding the great horse, dancing, fencing, vaulting, drawing fortifications, &c.

**EXERGASIA, Εξεργασία, Exposition, in Rhetoric,** a figure consisting of several equivalent expressions, or such as are nearly so, in order to represent the same thing in a stronger manner. The warmth and vehemence of the speaker often urge him to recur to this figure, when he is affected with his subject, and there are no words, no expressions, sufficiently forcible to express his sentiments; and he therefore repeats one after another, as his fancy suggests them. This flow of expression, under the conduct of a good judgment, is often attended with advantage; as it warms the hearers, and impresses their minds, excites their passions, and enables them to see things in a stronger light.

**EXERGUM, EXERGUE, or Exerge,** often denominated by Evelyn *exurge*, among *Medalists*, is the bottom of a coin, commonly separated from the field by a line, upon which the figures of the reverse stand. It is so called from being *εξ εργου*, out of the work of the medal. When the letters or words of a medal run round the margin, are on either side of the figure, or upon the exerge, they are denominated a *legend*; but when they occupy the field, they are called an *inscription*. See **LEGEND** and **INSCRIPTION**.

**EXETER, in Geography,** a city in Devonshire, England is of great antiquity, and, as Risdon emphatically styles it "may be called the emporium and principal ornament of the west." Its Roman name, as it appears in Ptolemy, is *Isca*; and it is conjectured that the second legion of Augustus was stationed here for some time: this was commanded by Vespasian, who was the conqueror of Britannia Prima, in which province this place was included. In the Itinerary of Antoninus, Exeter is called *Isca-Danmoniorum*, and is the most westerly station he has noticed: though, from the Iters of Ptolemy and Richard; from the remains of Roman roads over, and around Haldon; and from the vestiges of ancient ways through Drew-Teignton to Oakhampton, and perhaps of a road hence over Dartmoor, by Hollow-treet in the parish of Clagford; it is apparent that various principal roads ran westward from this city; and, therefore, it is probable that the Romans had other stations west of this. How long Exeter retained the name of *Isca-Danmoniorum* is uncertain; though it seems probable that it fell into disuse very soon after the Romans quitted the island, about which time it appears to have been re-occupied by the Britons who had preserved their independence by retiring to the wilds of Cornwall. They did not, however, continue in the possession of it many years; for Cerdic, the founder of the kingdom of Wessex, having greatly extended his territories, either by conquest or intrigue, included the most considerable portion of Devonshire within his dominions: and at length Exeter became subjugated to the power of the Saxons. Under their government its name was changed to *Evan-Cestre*, *Ex-Cestre*, &c., and thence, through various similar appellations, softened to Exeter.

This city has been several times besieged; but the greatest calamities it experienced were inflicted by the Danes, who, in the reign of Alfred, in violation of a solemn treaty, surprised and routed the king's horsemen, and mounting their steeds, rode to Exeter, and remained there for the winter. Alfred collected all his forces and invested the city by land, while his fleet blocked up the harbour: the Danes capitulated, and agreed to evacuate all the territories of the West Saxons. Between the period of the death of Alfred and the reign of Athelstan, the Cornish Britons had recovered possession of Exeter; but Athelstan having defeated and driven them to the west of the Tamar, they were never afterwards able to oppose the Saxon arms. To secure his conquests he surrounded Exeter with a wall of hewn stones defended by towers: and under his auspices, says Malmesbury, "it became such a place of trade, that it abounded with opulence." He adds that many other remarkable works of Athelstan were to be seen in the city and its neighbourhood. In the year 1003 Exeter was the first sacrifice to the fury of Swein king of Denmark, when he came to revenge the inhuman massacre of his countrymen: being delivered up by the treachery of its governor, after a siege of two months, many of the inhabitants were put to the sword, and most of the buildings destroyed by fire. Before it was well recovered from this calamity, it was again besieged and taken by William the Conqueror. In the reign of Stephen, this city was alternately garrisoned by the forces of the king and the empress. It again became the scene of hostility during the contest between Henry VI. and Edward IV. In the reign of Henry VII. it was closely, though ineffectually, besieged by three thousand men under Perkin Warbeck. The last siege Exeter experienced was in Edward VI.'s reign, when religious innovations occasioned an alarming insurrection in the west of England: the inhabitants, though reduced nearly to famine,

## EXETER.

so bravely defended the city for thirty-five days, that the insurgents abandoned their design.

The ground inclosed within the walls of the city is nearly in the form of a parallelogram, of four furlongs in length, and three in breadth: this space is intersected by the four principal streets which meet near the centre, and diverging at right angles, connect the city with the suburbs. The whole extent occupied by buildings is about one mile and three quarters in length, and one mile in breadth. In the year 1769 the surrounding walls were entire; but many parts have been since destroyed. Stukeley speaks of them as being, in his time, in pretty good repair, and having many turrets and towers, various parts of which are still remaining. Leland, speaking of this city, observes, that it is "a good mile and more in compass, and is right strongly waulid and maintainid. Ther be diverse fair towers in the toune waul bytwixt the south and the west gate. Ther be four gates in the toune, by the names of est, west, north, and south. The est and the west gates be now the fairest, and of one fascion of building: the south gate hath bene the strongest." In the year 1769 the north gate was taken down, to make a more convenient entrance into the city; and in 1784 the east gate was removed for the same purpose. The south gate, the interior arch of which Dr. Stukeley remarks to be of Roman workmanship, is intended to experience the same fate.

The situation of Exeter is commanding and pleasant: it stands on the acclivity of an eminence on the eastern banks of the river Exe, which flows in a semi-circular direction round the south-west side of the city. "What adds to its wholesomeness and cleanliness," says Stukeley, "is, that the ground is higher on a ridge along the middle of its length declining on both sides. Further, on the south-west and north-west sides it is precipitous; so that with the river, the walls, the declivity of ground, and ditch without side, 'twas a place of very great strength, and well chose for a frontier." In the highest part of the city, on the north side, stand the remains of Rougemont castle, which was formerly the seat of the West Saxon kings, and afterwards of the dukes of Exeter. This building has little to recommend it but its antiquity and pleasant situation. The ruins of the exterior walls are nearly all that remain; these inclose a considerable space, of a pentagonal form, and were defended by four towers; two on the west, and two on the east side. The ramparts of the castle command a most delightful view over the adjacent country. When the castle was erected is unknown; though Grafton's tale, that it was built by Julius Cæsar, is unquestionably false. William the Conqueror either rebuilt, or much repaired, the whole edifice, and bestowed it on Baldwin de Brion, husband of Albreda his niece, whose descendants, by the female line, enjoyed it, together with the office of sheriff of Devon, which seems to have been annexed to it, till the fourteenth year of Henry III.'s reign, when that prince, resuming into his own hands sundry castles and forts in this realm, dispossessed Robert de Courtney, in whose family it had been for three descents. In the civil war of the seventeenth century the castle was completely ruined, when the city withstood a blockade of two months against Fairfax, one of whose forts, Mr. Gough says, still remains in a field to the north. Within the area inclosed by the walls, a small chapel was erected by lady Elizabeth de Fortibus, countess of Devon, who endowed it with lands, called the prebends of Hays and Catton, for the payment of certain weekly services therein to be performed. A sessions-house, of Portland-stone, has been recently built within the area on the north-west side.

Within the walls of the city are fifteen parish churches, and in the suburbs four; but most of them being small, they present nothing worthy of particular description.

The cathedral is a large interesting edifice, and, according to Hooker and some other writers, was five hundred years in building; it consists of a nave with two aisles, a choir with aisles, a north and south transept, which are terminated by lofty towers. On the south side was a large cloister, which is mostly destroyed. To the east of this is the bishop's palace, which, with its gardens, are inclosed within a lofty wall. For a particular history and description with several architectural points, see a large folio work published by the Society of Antiquaries.

The episcopal see of Devon was seated at Crediton previous to its establishment at Exeter; but Leofric, who was bishop of that see, and lord chancellor of England, prevailed on Edward the Confessor to remove it to the latter town in the year 1049. That monarch, in person, with Eadýga, his queen, attended the installation, and placed the bishop in his new see; which at the same time he endowed with the lands and emoluments appertaining to that of Crediton. The see being thus established, it appears probable that a suitable cathedral was soon afterwards erected: but whether it was constructed by the enlargement and alteration of some existing edifice, or whether a separate and entire building was now raised, is uncertain. "It seems not unlikely," observes sir Henry Englefield, "that the first cathedral was not more than about sixty feet in length, and occupied the site of the present chapel of St. Mary." That the chapel, in its present state, was not the Saxon church, is satisfactorily proved by an examination of its architecture. No particular alteration appears to have been made in the cathedral before the time of William Warlewast, the third bishop, who was a Norman, and had been chaplain to the Conqueror, and his two sons, William and Henry; the latter of whom inducted him to this see in 1107. This prelate was a liberal benefactor to his cathedral; and it appears that he considerably enlarged it, and laid the foundation of the present choir: to him the towers yet remaining are probably to be ascribed; they are perfectly similar in style to the buildings of Gundulphus his cotemporary, and bear much more resemblance to the magnificence of the Norman architects, than to the simplicity of the English Saxons.

Exeter has been from time immemorial, and still is, invested with great privileges. At the period of the Norman survey it enjoyed the same exemption from taxes as London, York, and Winchester. Since that time it has obtained many charters, and grants of immunities, from several monarchs. In the reign of Henry I. the fee-farm rents were granted to Matilda his queen; and in king John's time, Isabel, his consort, held Exeter in dower, with a fair thereunto belonging. In the third year of John's reign, the burgesses paid a fine of 110 marks for a confirmation of their charters; and about this period the city, which had been previously governed by port-reves and bailiffs, was incorporated, and had a mayor for its chief officer. We find in the *Notitia Parliamentaria*, that "in the reign of Edward I. the burgesses and citizens pleaded that their city was an ancient demesne, and that they held it in fee-farm of the crown, paying 39*l.* 15*s.* 3*d.* To support this claim, they referred to Henry III.'s charter, made to his brother Richard, king of the Romans; whereby they further challenged return of writs, a gallows, pillory, &c. and a fair of four days, besides three weekly markets; which liberties they certified they enjoyed since the time of the conquest; upon which they were allowed." Henry VIII. constituted

constituted Exeter a county of itself; thus rendering it independent of Devon, and investing it with corresponding privileges.

The corporation now consists of a mayor, twenty-four aldermen, a recorder, chamberlain, town-clerk, sheriff, four stewards, and several inferior officers. The corporate bodies within the city are thirteen, each of which is governed by officers annually chosen from among themselves. Exeter was one of the first cities that returned members to parliament: the right of election is vested in the magistrates and freemen, who are supposed to amount to about one thousand persons. The trade of Exeter is extensive; yet would probably have been much more so, but for a contention between the inhabitants and Hugh Courtenay, earl of Devon, which deprived the city of the use of its river for navigable purposes during several centuries. The dispute is reported by Izacke to have arisen about some pots of fish; which, being exposed for sale in the market place, were seen nearly at the same time by the caters of the earl, and of the bishop of Exeter, both of whom wanted the whole. The mayor, to whom the difference was referred, adjudged one part to the earl, another to the bishop, and the third he directed to be kept for the use of the market. This decision, and a subsequent determination of the mayor and council, that no freeman of Exeter should wear any foreigner's livery, badge, or cognizance without the mayor's licence, offended the earl, who immediately impeded the navigation of the river, "stopping, filling, and quirting the same," says Hooker, "with great trees, timber, and stones, in such sort, that no vessel, or vessels, could pass or repass." Previously to this occurrence the tides flowed beyond the city; but now they only reach Topsham, a town between three or four miles nearer the sea, the advantage of which was probably the chief object of the earl's measures, as that place was part of his estate, and became exceedingly flourishing in consequence. The river was so completely choaked up, that though many attempts were made to restore the navigation, scarcely any thing was accomplished till the year 1675, when a canal was cut from Topsham to the city; and about twenty years afterwards the present haven was constructed: and by means of sluices and flood-gates, vessels of 150 tons burthen are now admitted to a good quay, formed near the city walls.

Exeter is situated 170 miles W. from London. The number of inhabitants, as returned under the late act, was 17,388; of houses 2836. The principal employ of the labouring classes of people arises from the woollen trade; and the city has derived immense profits from the exportation of serge, kerseys, and other articles, the value of which together has been computed at the average sum of 600,000*l.* per annum: the chief markets were, during peace, Spain, Portugal, Germany, and Italy. About 300 persons are also employed in manufacturing cotton, at a large factory established on the banks of the river. Exeter had anciently a mint, which was granted by king Athelstan; and money has been coined here so late as the reign of William III., the place of coinage being denoted by the letter E under the bust.

This city has been the birth place of several very eminent and learned men. Among the most distinguished are, Josephus Iscanus, whose writings adorned the commencement of the thirteenth century: John Hooker, sir William Petre, and sir Thomas Bodley, who all flourished in the sixteenth century; and sir Peter, afterwards lord King, who held the high office of lord chancellor from 1725 to 1733.

In the vicinity of Exeter are several handsome, and re-

spectable seats, belonging to the nobility and gentry. The principal of these are, Powderham-castle, belonging to viscount Courtney; Mannhead, the seat of lord Luburne; Haldon-house, the seat of sir Lawrence Palk, &c.; Mount-Radford, the seat of John Baring, esq.; Peamore, the seat of Samuel Kekewich, esq.; Cleve, the seat of Thomas Northmore, esq.; Cowicke, the seat of James White, esq.; Oxtou-house, the seat of the Rev. John Swete. Polwhele's History of Devonshire, 8vo. Jenkins's History and Antiquities of Exeter, 12mo. 1806.

EXETER, a post-town of America, in the county of Rockingham and state of New Hampshire, and, Portsmouth excepted, the most considerable sea-port town in the state. It is situated on the head of the navigation on Swamscot; or Exeter river, a branch of the Piscataqua, 15 miles S.W. of Portsmouth. The tide rises here eleven feet. This town is well situated for manufactures, and has already six saw mills, a fulling mill, flitting mill, paper mill, snuff mill, two chocolate and ten grist mills, iron-works, and two printing offices. The sallery business is very considerable. Some few vessels of different burden are built here, and the river is capable of floating those of 500 tons. The situation of Exeter is adapted for an extensive population. The public edifices are, two congregational churches, an elegant building appropriated to the academy, a handsome and capacious court-house, and a gaol. The public offices of the state are at present kept in this place. It contains 1727 inhabitants. The township is of an irregular figure, and about four miles square. It was incorporated in 1638, before which period it was called Swamscot falls; it lies 50 miles N. of Boston. N. lat. 42° 59'. W. long. 71°. The academy was founded and endowed by the Hon. John Phillips, L.L.D. of Exeter, and incorporated by act of assembly in 1781. It is said to be a respectable institution, under the inspection of a board of trustees, and the immediate government and instruction of a preceptor and an assistant. Its annual income is 480*l.* and the number of students is commonly between 60 and 80. In 1794 a building was erected, which, in point of convenience, and perhaps of elegance, is exceeded by few buildings of the kind in the United States. Morse.

EXETER, the north-westernmost township in Washington county, and state of Rhode island, in which the several branches of Wood river unite; containing 2476 inhabitants, of whom 24 are slaves.—Also, a township in Luzern county, Pennsylvania, including 737 inhabitants.—Also, a town in New Hanover county, in Wilmington district, North Carolina; situated on the N.E. branch of Cape Fear, about 36 miles from Wilmington.

EXFOLIATION. This term, in *Surgery*, denotes the process by which the dead part of a bone separates from the living portion. It is also not uncommon for surgeons to signify, by the word *exfoliation*, the piece of bone itself that has perished, though this is certainly an abuse of language.

Exfoliation, or the separation of a dead portion of bone from the living, is effected much in the same way as a slough is thrown off from the soft parts. The piece of bone which has perished is not detached by becoming rotten; for, in fact, it possesses considerable firmness, and at first coheres as intimately as ever to the living bone immediately contiguous to it. As Mr. Hunter has accurately observed, if the process of exfoliation were not to take place, the dead piece of bone would remain undetached for years, inasmuch as putrefaction is concerned in producing the separation.

The more the pathologist considers the diseases of the bones

## EXFOLIATION.

bones, the more he will find them resemble those of the soft parts. This fact, indeed, anatomy would lead one to infer, since the texture of the bones is the more similar to the structure of the rest of the body, than an uninformed person would suppose. The chief difference is, that the bones contain lime, which the soft parts do not.

Mr. Hunter describes the process of exfoliation as follows; a dead bone (he says) acts on the system in the same manner as any other extraneous body. It stimulates the adjacent living parts, in consequence of which such a process is begun, as must end in the dead piece being thrown off. The effects of this stimulus are; first, that the living adjacent bone becomes more vascular, a circumstance which always takes place, when a part has more to do than is just sufficient for the support of life. Secondly, that the earth of the living part, when it is in contact with the dead bone, is absorbed. Hence the bone becomes softer, and is now only adherent by the animal matter in its texture. Thirdly, that the living animal part is at last absorbed along the surfaces of contact. This part of the process begins long before the last is finished. Both of them begin first at the surface, though, in their course, they do not every where take place, in an equal degree, at the same time. Fourthly, that, in proportion to the waste made by the last part of the process, a fungus arises from the living surface, and fills up the intermediate space, so as to prevent a vacuum. Mr. Hunter observes, that these different stages, taken together, constitute ulceration. He remarks, that when any part of a bone is once loose, it will be pushed towards the surface of the body, as most other inanimate substances are. This part of the process is partly mechanical, and partly a continuation of ulceration. The same distinguished surgical writer also notices, that a proof of the third stage above mentioned, may be derived from certain cases, in which people die while exfoliation is going on. A small groove, or worm-eaten canal, may then be discovered, which becomes gradually deeper, and follows the irregularities of the dead and living surfaces. After the application of the trepan, a circular piece of bone is frequently thrown off, which is always less than the space from which it came. This, says Mr. Hunter, could never be the case, if there were not a loss of substance.

Thus we find that exfoliation, and the process by which a slough of the soft parts is detached, are nearly alike. In both instances, the matter which forms the bond of connection between the dead and living substances, is absorbed, the dead part is loosened, and is next pushed off by the rising of the granulations.

The bones, on which exfoliations most frequently occur, are such as are of a firm, solid structure; those which are of a spongy cellular texture, are more subject to the affection called caries.

All the old surgical practitioners and writers used to promulgate the doctrine, that whenever the surface of a bone was laid bare, and deprived of its periosteum, an exfoliation must inevitably follow. The practice, which was resorted to in consequence of this notion, did really, for the most part, occasion a destruction of a part of the bone, and the progress of the case seemed a confirmation of the erroneous opinion, resting on experience itself for its foundation. For it followed almost as a matter of course with the ancient surgeons that since they considered the occurrence of exfoliation unavoidable in the circumstance which we have mentioned, their grand aim was to promote and accelerate the process, so as to shorten, as they conceived, the duration of the case. With this view, they used to put on the uncovered part of the bone stimulating, drying, spirituous applications, and,

very often, the actual and potential cautery. Also, fancying that the wound could never heal till the dead piece of bone had come away, they used to avoid laying down the flesh, so as not to leave the surface of the bone a long while exposed, a cause, of itself, quite adequate to the production of an exfoliation.

However, the fact is, that a mere temporary exposure of part of a bone, such a transient denudation, as need only be permitted in cases of wounds, is not necessarily, or even commonly followed by an exfoliation, when a proper method of treatment is pursued.

We have already remarked that the diseases of the bones are more like those of the soft parts, than many would imagine. The exposed surface of a bone will not die, if it be otherwise free from injury, and the surgeon, immediately he is called, take care to lay down the detached flesh in the situation which it previously occupied. Even when the denuded bone, on account of loss of substance, cannot be directly covered again, it will not always exfoliate, provided the surgeon, instead of using the cautery, caustics, spirituous, or any other irritating applications, applies only some plain soft lint, or a pledget of any mild simple ointment.

When the soft parts are merely divided, the exposed surface will not slough; but when the wound is complicated, with a violent degree of contusion, laceration, &c. the case is different, and the fibres, vessels, &c. most injured, will die and be thrown off. These parts may either be killed at once by the violence, or the mischief which they have sustained may give rise to inflammation, which may terminate in sloughing. Things are nearly the same with respect to the bones. We will bring to our consideration a few circumstances relating to the subject of wounds of the head, which are, perhaps, more frequently than any other kind of wounds followed by exfoliations. In these instances, if the soft parts be simply cut, so as to occasion an exposure of the cranium, without the bone itself being violently contused, the wound may be healed by the first intention, and no part of the skull will exfoliate. The same occurrences may happen, together with a detachment of the pericranium, and yet the same consequences will follow.

However, when the external violence has affected the bone, as well as the soft parts, the injured part of the skull will frequently die and exfoliate, notwithstanding the most judicious treatment.

The process by which an exfoliating piece of bone is thrown off, depends almost entirely upon nature, and the surgeon can interfere very little, with any real utility. The milder and less irritating his dressings are, the better. Sometimes, when the dead part of the bone is loose, but is so covered with flesh that it cannot come away, the practitioner may greatly expedite the cure, by making a proper opening for the removal of the piece of bone that has exfoliated. Sometimes, when the process of exfoliation is long and tedious, he may render essential aid by occasionally introducing a pair of small forceps into some sinus leading down to the affected bone, and moving the exfoliating portion a little every now and then, so as to accelerate its separation. This latter proceeding, it is obvious, is only admissible when the opening in the soft parts is large enough, and when the dead piece of bone either projects, or is of such a shape as will allow of its being taken hold of with a pair of forceps. Sometimes, when the dead piece of bone is prevented from exfoliating, by being overlapped by new osseous matter at its circumference, the surgeon may properly make some attempt to cut away the portion which is so wedged, that its spontaneous detachment would require an unreasonable length of time. Endeavours of this kind, however, on the

part of the surgeon, should be made with great circumspection and prudence; and, indeed, they can only be justifiable when the affected bone is sufficiently superficial.

**EXFOLIATIVUM**, from *exfolio*, to *shed the leaf*, an instrument for scraping exfoliating bones.

**EXFREDIARE**, in our *Old Writers*, denotes the breaking of the peace, or committing open violence. Leg. Hen. I. cap. 31.

The word is formed from the Saxon, *frede*, peace.

**EX GRAVI QUERELA**, in *Law*, a writ that lies for him to whom any lands or tenements in fee are devised by will (within any city, town, or borough, wherein lands are devisable by custom), and the heir of the devisor enters, and detains them from him. (Reg. Orig. 244. Old Nat. Br. 87.) And if a man devises such lands or tenements unto another in tail, with remainder over in fee, if the tenant in tail enter, and is seised by force of the entail, and afterwards dieth without issue, he in the remainder shall have the writ, *ex gravi querela*, to execute that devise. (New Nat. Br. 441.) Also where a tenant in tail dies without issue of his body, the heir of the donor, or he who hath the reversion of the land, shall have this writ in the nature of a *formedon in the reverter*. Ibid.

If a devisor's heir be ousted by the devisee, by entry on the lands, he may not afterwards have this writ, but is to have his remedy by the ordinary course of the common law. (Co. Litt. 111.) If the claimant's title accrues within 20 years, the most eligible method of proceeding, is now by *ejectment*; which see.

**EXHÆREDATIO**. See EXHEREDATION.

**EXHALATION**, a fume or steam exhaling or issuing from a body, and diffusing itself in the atmosphere.

The terms exhalation and vapour are ordinarily used indifferently, but the more accurate writers distinguish them; appropriating the term vapour to the moist fumes raised from water and other liquid bodies; and exhalation to the dry ones emitted from solid bodies, as earth, fire, minerals, sulphurs, salts, &c. In this sense, exhalations are dry subtile corpuscles, or effluvia, loosened from hard terrestrial bodies, either by the heat of the sun, or the agitation of the air, or some other cause, and emitted upwards to a certain height of the atmosphere, where, mixing with the vapours, they help to constitute clouds, and return back again into dews, mists, rains, &c.

Sir Isaac Newton takes true and permanent air to be formed from the exhalations raised from the hardest and most compact bodies. See AIR, DAMP, EVAPORATION, and VAPOUR.

**EXHAUSTED RECEIVER**, a glass, or other vessel, applied on the plate of an air-pump, and having the air extracted out of it by the working of the engine. (See AIR-pump.) Things placed in an exhausted receiver, are said to be *in vacuo*. See VACUUM.

**EXHAUSTIONS**, in *Mathematics*. Method of exhaustions is a way of proving the equality of two magnitudes, by a *reductio ad absurdum*; shewing, that if one be supposed either greater or less than the other, there will arise a contradiction. The method of exhaustions was of frequent use among the ancient mathematicians, as Euclid, Archimedes, &c. It is founded on what Euclid says in his tenth book, *viz.* that those quantities whose difference is less than any assignable quantity, are equal; for if they were unequal, be the difference ever so small, yet it may be so multiplied, as to become greater than either of them; if not so, then it is really nothing.

This he assumes in the proof of prop. 1. book x. which imports, that if, from the greater of two quantities you take

more than its half, and from the remainder more than its half, and so continually, there will, at length, remain a quantity less than either of those proposed.

On this foundation it is demonstrated, that if a regular polygon of infinite sides be inscribed in or circumscribed about a circle, the space, which is the difference between the circle and the polygon, will by degrees be quite exhausted and the circle become equal to the polygon.

**EXHEBENUM**, in *Natural History*, the name of a white and smooth stone, used by the ancient artificers in polishing gold. It seems to be the same with the lapis Samius, a small smooth stone which they often found in the Samian earth.

**EXHEREDATION**, **EXHÆREDATIO**, in the *Civil Law*, with us ordinarily called disinheriting, is the father's excluding his son from inheriting his estate.

There are fourteen causes of exheredation expressed in Justinian's Novel; without some one of which causes, he decrees the exheredation null, and the testament inofficious, as the civilians call it.

Indeed, by the ancient Roman law, the father might pronounce exheredation without any cause; but the rigour of this law was restrained and moderated by Justinian.

**EXHIBIT**, in *Law*. When a deed, acquittance, or other writing is, in a chancery suit, exhibited, to be proved by witness, and the examiner writes on the back, that it was shewed to the witness at the time of his examination; this is called an exhibit.

**EXHIBITION**, a producing or shewing of titles, authorities, and other proofs of a matter in contest.

Anciently, they used the phrase, exhibition of a tragedy, comedy, or the like; but now we say representation in lieu thereof.

**EXHIBITION**, *Exhibitio*, in our *Old Writers*, is used for an allowance of meat and drink, such as was customary among the religious appropriators of churches, who usually made it to the depending vicar. The benefactions settled for the maintaining of scholars in the universities, not depending on the foundation, are also called exhibitions.

**EXHORTATION**, **HORTATIO**, in *Rhetoric*, differs only from *suasion*, in that the latter principally endeavours to convince the understanding, and the former to work on the affections.

**EXHUMATION**, of *ex*, out of, and *humus*, ground, the act of digging up a body interred in holy ground, by the authority of the judge.

In France, the exhumation of a dead body is ordered, upon proof that he was killed in a duel. By the French laws, a parson has a right to demand the exhumation of the body of one of his parishioners, when interred out of the parish without his consent.

**EXIDEUIL**, in *Geography*, a town of France, in the department of Dordogne, and chief place of a canton, in the district of Perigueux; 18 miles N. E. of Perigueux. The place contains 870, and the canton 8378 inhabitants, in 15 communes, and on a territorial extent of 190 kilometres.

**EXIGENCE**, or **EXIGENCY**, that which a thing requires, or which is expedient and suitable thereto.

**EXIGENT**, or **EXIGI FACIAS**, in *Law*, a writ which lies where the defendant, in a personal action, cannot be found, nor any thing of his within the county, whereby to be attached, or distrained. It is directed to the sheriff, ordering him to proclaim and call the party five county-court days successively, and charge him to appear, under pain of outlawry.

The same writ also lies in an indictment of felony, where the party indicted cannot be found.

It is called an exigent, because it exigit, *i. e.* exacts, or requires the party to appear, or, by forthcoming, to answer the law. If he appear not at the last day's proclamation, he is said to be *quingies*, or *quinto exactus*, and then is outlawed. See OUTLAWRY.

EXIGENTERS, four officers of the court of common pleas, who make all exigents and proclamations, in all actions where the process of outlawry lies.

Anciently, the making writs of *superseas* upon such exigents as passed in their offices, did likewise belong to them; but this branch of business was taken from them under king James I. and committed to a particular officer in the court of common pleas, created by patent. See SUPERSEDEAS.

EXILE, BANISHMENT. See BANISHMENT.

Among the Romans, the word exile, *exilium*, properly signified an interdiction or exclusion from water and fire; the necessary consequence of which was, that the interdicted person must betake himself into some other country, since there was no living without fire and water. Thus Cicero ad Herenn. observes, that the form of the sentence did not express exile, but only *aque & ignis interdictio*. See INTERDICTION.

The same author remarks, that exile was not properly a punishment, but a voluntary flying, or avoiding the punishment decreed: "Exilium non esse supplicium, sed perfugium, portusque supplicii." Pro Cæcina.

He adds, that there was no crime among the Romans, as among other nations, punished with exile; but exile was a recourse people flew voluntarily to, in order to avoid chains, ignominy, starving, &c.

The Athenians frequently sent their generals, and great men into exile, out of envy of their merits, or distrust of their too great authority.

EXILE is sometimes also used for the relegating a person into a place, whence he is obliged not to stir without leave.

The word is derived from the Latin *exilium*, or from *exul*, a banished person; and that, probably, from *extra solum*, out of his native soil.

Figuratively, we use the phrase, *honourable exile*, for an office, or employment, which obliges a man to reside in some remote or disagreeable place.

Under the reign of Tiberius, remote employments were a kind of mysterious exiles. A bishopric, or even a lord-lieutenancy, in Ireland, has been sometimes deemed a kind of exile. A residence, or embassy, in some barbarous country, is also a sort of exile. Accordingly, it is said, that the king cannot even constitute a man deputy, or lord-lieutenant of Ireland, nor make one a foreign ambassador against his will, since these in reality might be no more than honourable exiles. 2 Inst. 46.

EXILES, in *Geography*, a town of France, in the department of the Po, on the river Doria; 5 miles W. S. W. of Susa. This town was fortified, and guarded one of the passes into Piedmont; but by the treaty of peace between the French republic and the king of Sardinia, in 1796, the fortifications were to be razed.

EXILIUM, in *Law*, signifies a spoiling; and, by the statute of Marlbridge, it seems to extend to the injury done to tenants, by altering their tenure, ejecting them, &c. And this is the sense that Fleta determines; who distinguishes between *vastum*, destruction, and *exilium*. For he tells us, that *vastum* and *destructio* are almost the same, and are properly applied to houses, gardens, or woods; but

*exilium* is when servants are enfranchised, and afterwards unlawfully turned out of their tenements. Flet. lib. i. cap. 11. Stat. Marl. cap. 25.

EXIMA, in *Geography*, a tribe or kabyle in the province of Susa, in the southern division of Morocco; amounting to about 11,000 persons.

EXIMENO, ANTONIO, in *Biography*, a Spanish Ex-Jesuit, who had resided at Rome many years, and published in that city, in 4to. 1744, a work, intitled "Dell' Origine e della Regole della Musica," in which, too confident of his own powers, he imagined himself capable, with four years study only, intuitively to frame a better system of counterpoint than that upon which so many great musicians had been formed. Possessed of eloquence, fire, and a lively imagination, his book has been called in Italy, "a whimsical romance upon the art of music, in which is discovered a rage for pulling down, without the power of rebuilding." The author has certainly, with shrewdness and accuracy, started several difficulties, and pointed out imperfections in the theory and practice of music, as well as in the particular systems of Tartini and Rameau; but his own resources and experience are totally insufficient to the task of correcting the errors of the old system, or forming a new one that is more perfect. He has more eloquence of language than science in music. His reasoning is ingenious and specious, even when his data are false; but his examples of composition are below contempt; and yet, they are courageously given as models for students, superior to those of the old great masters of harmony.

When Sig. Eximeno calls fugues and canons Gothic compositions, he does not disgrace their structure any more than he would our cathedrals, by calling them Gothic buildings. Let fugues be banished from the theatres and private concerts, if he pleases, and let them remain in the church as a distinct species of composition, where they were first generated, and where they can never become vulgar or obsolete. The style being naturally grave, requires musical learning, and will, by the solemnity of the words and place of performance, continue to be revered and respected. It is allowed that variety is more wanted in music than in any other art, and by totally excommunicating canons and fugues from the church, the art will lose one capital source of variety, as well as ingenuity; and intelligent hearers will be deprived of a solemn style of music, to be heard no where else.

EXINANITION, the same as evacuation.

EXISTENCE, that whereby a thing has an actual essence, or is said to be, *esse*.

The notion of existence is applicable not only to a created but an uncreated substance: but it must be added, that the existence of created substances, and especially corporeal ones, implies a respect to place, time, and even an efficient cause; whence the schoolmen generally define it, that whereby a thing is formally and extrinsically without [*extra*] its causes, and that here, and now.

Existence and essence come very near the nature of each other; in effect, they only differ in that we have different manners of conceiving the same thing.

For, 1. Essence is usually explained either by the first, noblest, and radical attribute of the thing, *e. gr.* that of body, by extension; that of mind by thinking, &c. or by specifying all the intrinsic attributes; and existence, either by specifying all place and all time, as in that of God; or by specifying some definite place, and time, together with the cause, as in the creatures.

2. The foundation and occasion of this distinction is

## EXISTENCE.

this: that essence belongs to the question, *What is it?* *Quid est?* but existence to the question, *Is it? An est?*

3. Existence, necessarily pre-supposes essence, and cannot be conceived without it; but essence may be conceived without existence; in that essence belongs equally to things that are in *potentia*, and in *actu*; but existence only to those in *actu*. Note, however, that this does not obtain in God, about whose nature and essence the mind cannot think without conceiving his existence.

We have divers ways of arriving at the knowledge of the existence of things. Our own existence we know by intuition; the existence of a God, by demonstration; and that of other things, by sensation.

As for our own existence, we perceive it so plainly, that it neither needs, nor is it capable of any proof. In every act of sensation, reasoning, or thinking, we are conscious to ourselves of our own being, and in this matter come not short of the highest degree of certainty.

As to our knowledge of the existence of a God, though he has given us no innate ideas of himself, yet, having furnished us with faculties of sense, perception, and reason, we can never want a clear proof thereof. See God.

The knowledge of the existence of other things, *i. e.* of external objects, bodies, a world, &c. we only have by sensation; for there being no necessary connection of real existence with any idea a man hath in his memory, nor of any other existence but that of God, with the existence of any particular man; no particular man can know the existence of any other being, but only when, by actually operating upon him, it makes itself be perceived by him. The having the idea of any thing in our mind, no more proves the existence of that thing than the picture of a man evidences his being in the world, or the visions of a dream make a true story. It is, therefore, the actual receiving of ideas from without that gives us notice of the existence of other things, and makes us know that something doth exist at that time without us, which causes that idea in us, though we neither know nor consider how it doth it.

This notice which we have by our senses, of the existence of things without us, though it be not altogether so certain as intuition and demonstration, yet deserves the name of knowledge, if we persuade ourselves that our faculties act and inform us right concerning the existence of those objects that affect them.

Now, besides the assurance of our senses themselves, that they do not err in the information they give us of the existence of things without us, we have other concurrent reasons, as, 1. It is plain those perceptions are produced in us by exterior causes affecting our senses; because those that want the organs of any sense never have the ideas belonging to that sense produced in their minds. 2. Because we find we cannot avoid having those ideas, produced in our minds. When our eyes are shut, we can at pleasure recal to our mind the ideas of light or the sun, which former sensations had lodged in our memories; but if we turn our eyes towards the sun, we cannot avoid the idea which the light or the sun then produces in us, which shews a manifest difference between those ideas laid up in the memory, and such as force themselves upon us, and we cannot avoid having; besides, there is no one who doth not perceive the difference in himself between actually looking upon the sun, and contemplating the idea he has of it in his memory; and therefore he hath certain knowledge, that they are not both memory or fancy. 3. Add to this, that many ideas are produced in us with pain, which we afterwards remember without the

least offence; thus, the pain of heat or cold, when the idea of it is received in our mind, gives us no disturbance, which, when felt, was very troublesome; and we remember the pain of hunger, thirst, head ach, &c. without any pain at all, which would either never disturb us, or else constantly do it, as often as we thought of it, were there nothing more but ideas floating in our minds, and appearances entertaining our fancies, without the real existence of things affecting us from abroad. 4. Our senses, in many cases, bear witness to the truth of each other's report concerning the existence of sensible things without us: he that doubts, when he sees a fire, whether it be real, may feel it too if he pleases; and, by the exquisite pain, may be convinced, that it is not a bare idea or phantom. Such is Mr. Locke's demonstration of the existence of external bodies.

The ingenious Dr. Berkeley has a different system: external bodies, he contends, have no existence, but in a mind perceiving them; that is, they only exist, *quatenus*, they are perceived; and of this he has given us what he and several others account a demonstration.

In reality, "that neither our thoughts, passions, nor ideas formed by the imagination, exist without the mind, he observes, is allowed; and that the various sensations impressed on the mind, whatever objects they compose, cannot exist otherwise than in a mind perceiving them, is not less evident. This appears from the meaning of the term exist, when applied to sensible things. Thus, the table I write on, exists, *i. e.* I see and feel it; and were I out of my study, I should say it existed; *i. e.* that were I in my study I should see and feel it as before. There was an odour; *i. e.* I smelt it, &c. but the existence of unthinking beings, without any relation to their being perceived, is unintelligible, their *esse* is *percipi*." The notion of bodies, he endeavours to shew, is founded on the doctrine of abstract ideas: "What are light and colours, heat and cold, extension and figure; in a word, the things we see and feel, but so many sensations, notions, ideas, or impressions on the sense? And is it possible to separate, even in thought, any of these from perception? The several bodies, then, that compose the frame of the world, have not any subsistence without a mind: their *esse* is to be perceived or known; and as long as they are not perceived by me, nor any other thinking being, they have no shadow of existence at all. The things we perceive are colour, figure, motion, &c. that is, the idea of those things; but has an idea any existence out of the mind? To have an idea is the same thing as to perceive; that, therefore, wherein colour, figure, &c. exist, must perceive them. It is evident, therefore, there can be no unthinking substance or substratum of those ideas: but you may argue, if the ideas themselves do not exist without the mind, there may be things like them, whereof they are copies or resemblances, which exist without the mind; it is answered, an idea can be like nothing but an idea; a colour or figure can be like nothing else but another figure or colour. It may be farther asked, whether those supposed originals, or external things, whereof our ideas are the pictures, be themselves perceivable or not? If they be, they are ideas; if they be not, I appeal to any one, whether it be sense to say, a colour is like somewhat which is invisible; hard or soft, like somewhat intangible, &c. Some distinguish between primary and secondary qualities; the former, *viz.* extension, solidity, figure, motion, rest, and number, they maintain have a real existence out of the mind; as for the latter, under which come all other sensible qualities, as colours, sounds, tastes, &c. they allow the ideas we have of them are not resemblances of any things existing

## EXISTENCE.

existing without the mind, or unperceived, but depend on the size, texture, motion, &c. of the minute particles of matter. Now, it is certain, that those primary qualities are inseparably united with the other secondary ones, and cannot even in thought be abstracted from them, and therefore must only exist in the mind. Can any man conceive the extension and motion of a body without its other sensible qualities? For my part, I find it impossible to frame an idea of a body extended and moving, without giving it some colour, &c. In effect, extension, figure, and motion, abstracted from all other qualities, are inconceivable; where the others, therefore, are, there these too must be, *i. e.* in the mind, and no where else. Again, great and small, swift and slow, are allowed to exist no where without the mind, being merely relative and changing, as the frame or position of the organ changes: the extension, therefore, that exists without the mind, is neither great nor small, the motion neither swift nor slow; *i. e.* they are nothing. That number is a creature of the mind, is plain (even though the other qualities were allowed to exist) from this; that the same thing bears a different denomination of number, as the mind views it with different aspects; thus, the same extension is 1, or 3, or 36, as the mind considers it, with reference to a yard, a foot, or an inch. Nay, many of the modern geometricians hold, that a finite line may be divided into an infinite number of parts, and each of these infinitesimals, into an infinity of others; and so on, *in infinitum*; so that the same thing is either unity or infinity, either no number or all number. In effect, after the same manner as the modern philosophers prove colours, tastes, &c. to have no existence in matter, or without the mind; the same thing may be proved of all sensible qualities whatsoever: thus, they say, heat and cold are only the affections of the mind, not at all patterns of real beings existing in corporeal substances; because the same body which seems cold to one hand, seems warm to another. Now, why may we not as well argue, that figure and extension are not patterns or resemblances of qualities existing in matter; because to the same eye, at different stations, or to eyes of different structure, at the same station, they appear various? Again, sweetness, it is proved, does not exist in the thing sapid, because the thing remaining unaltered, the sweetness is changed to bitterness, as in a fever, or by an otherwise vitiated palate. Is it not as reasonable to say, that motion does not exist out of the mind? since, if the succession of ideas in the mind become swifter, the motion, it is acknowledged, will appear slower, without any external alteration. Again, were it possible for solid figured bodies to exist out of the mind, yet it were impossible for us ever to know it: our senses, indeed, give us sensation of ideas, but do not tell us that any things exist without the mind, or unperceived, like those which are perceived: this the materialists allow. No other way therefore remains, but that we know them by reason's inferring their existence from what is immediately perceived by sense. But how should reason do this, when it is confessed, there is not any necessary connection between our sensations and these bodies? It is evident, from the phenomena of dreams, phrensies, &c. that we may be affected with the ideas we have now, though there were no bodies existing without them; nor does the supposition of external bodies at all forward us, in conceiving how our ideas should come to be produced. The materialists own themselves unable to conceive in what manner body can act on spirit, or how it should imprint any idea on the mind. To suppose, therefore, bodies existing without the mind; is little else than to suppose God has created innumerable beings entirely useless, and serving to no purpose at all. On the whole it appears, that the existence of bo-

dies out of a mind perceiving them, is not only impossible, and a contradiction in terms; but, were it possible, nay real, it were impossible we should ever know it. And again, that supposing that there are no such things, yet we should have the very same reason to suppose there were that we now have. Suppose, *e. gr.* an intelligence affected with the same train of sensations, impressed in the same order, and with the same vividness, would it not have all the reason to believe the existence of bodies represented by his ideas that we have? All our ideas and sensations are visibly inactive; nay, the very being of an idea implies passiveness and inertness; so that it is impossible for an idea to do any thing, or, in strictness, be the cause of any thing; it cannot, therefore, be the resemblance or pattern of any active being, unless opposites can be said to resemble one another. Now, we find a continual succession of ideas of the mind; but these, it has been proved, do not depend on any external body as their cause; it remains, therefore, that their cause is an incorporeal active substance or spirit: for that I am not the cause of my own ideas, is plain from this, that when I open my eyes in broad day-light, I cannot help seeing various objects. Now, the fixed rules or methods wherein the mind we depend on excites in us the ideas of sense, are called *laws of nature*; these we learn by experience, which teaches us, that such and such ideas are attended with such and such other ideas in the ordinary course of things. Ideas are not any how, and at random, produced; there is a certain order and connection established among them like that of cause and effect; and there are several combinations of them made in a very regular artful manner, which we call *bodies*; and the system of those, *the world*. In strictness, however, the connection of ideas does not imply the relation of cause and effect, but only of a mark or sign of the thing signified: the fire I see is not the cause of the pain I feel, but the mark that forewarns me of it; the noise I hear is not the effect of this or that motion or collision of natural bodies, but the sign thereof. The Cartesians own somewhat like this: the action of bodies on our organs, say they, is not the efficient cause of our ideas and perceptions, but only the occasional cause, which determines God to act on the mind, according to the laws of the union of the soul and body." (See CAUSE.) Dr. Berkeley, indeed, taking away bodies, takes away what these philosophers account the occasions of their ideas: "by an occasion, he says, must either be meant the agent that produces an effect, or something observed to accompany or go before it in the ordinary course of things; but matter is allowed to be passive and inert, and cannot therefore be an agent or efficient cause; and this matter primitively, and in itself, is allowed imperceivable, and devoid of all particular sensible qualities; *i. e.* it has not this or that particular colour, this or that particular figure, &c. but has colour in the general, figure in the abstract, &c. but an abstract is no object of sense; matter, therefore, cannot be the occasion of our ideas in the latter sense." See BERKELEY. Princip. of Human Knowl. See ABSTRACTION.

How far the great argument of the maintainers of a material world from the impossibility of God's deceiving us, and from the evidence that he does so, if there be no such thing, will go against this reasoning, we leave to the reader. See Stanl. Hist. Philosoph. part xii. p. 816. where the objections of the ancient Pyrrhonist to the existence of bodies are recited.

As to the existence of spirits, Mr. Locke allows, that our having ideas of them does not make us know that any such things do exist without us; or that there are any finite spirits, or any other spiritual beings, but God. We have ground

ground from revelation, and several other reasons, to believe with assurance, that there are such creatures; but our senses, being not able to discover them, we want the means of knowing their particular existence; for we can no more know that there are infinite spirits really existing by the idea we have of such beings, than by the ideas any one has of fairies or centaurs, he can come to know that things answering to those ideas do really exist.

EXIT, properly expresses the departure of a player from off the stage, when he has acted his part.

The word is also used in a figurative sense, to express an kind of departure, even death.

EXITERIA, Ἐξίτηριαι, in *Antiquity*, oblations or prayers to any of the gods for a prosperous expedition or journey. There were also feasts under this denomination, which were celebrated by the Greeks, with sacrifices and prayers, when their generals undertook expeditions against any enemy.

EXITURA, from *exeo*, to come from, in *Surgery*, an abscess which discharges matter.

EXITUS, ISSUES, in *Law*, the yearly rents or profits of lands or tenements. See *ISSUE*, &c.

EXLEGALITUS, the same with an outlawed person. See *OUTLAW*.

EXLUNZA, in *Geography*, a town of Spain, in the province of Leon; 5 miles S. E. of Leon.

EX MERO MOTU, in *Law*, formal words used in the king's charters and letters patent, signifying that he does what is contained therein of his own will and motion, without petition or suggestion of any other.

The effect of these words is to bar all exceptions that might be taken to the instrument, by alleging that the prince in passing such charter was abused by false suggestions.

EXMES, in *Geography*, a town of France, in the department of the Orne, and chief place of a canton in the district of Argentan; 9 miles E. of Argentan. The place contains 618, and the canton 7358 inhabitants, in 31 communes, and on a territorial extent of 147½ kilometres.

EXMOUTH, though a watering place of considerable size and repute, is only a hamlet belonging to the parish of Littleham, in the county of Devon, England. As its name imports, it stands near the mouth of the river Exe. The buildings in general are low, but here are some good houses inhabited by genteel families. The vicinity is highly picturesque: from an eminence, called Chapel-hill, a line of coast presents itself, which extends from Exeter to Berry-head, a distance of about twenty miles. This line is broken by several hills, behind which spring up some bold towering head-lands.

The plantations of Mamhead and Powderham-castle heighten the beauty of the prospect; which is additionally embellished by the noble buildings connected with those estates. Holinshed mentions a castle erected here to defend the entrance of the haven; and some slight vestiges of embrasures are still apparent. Exmouth is situated 168 miles W. from London; and contains, including the parish of Littleham, 432 houses, and 1909 inhabitants, of whom 570 are returned as employed in trade or manufacture. Polwhele's *Devonshire*, vol. ii.

EXOACANTHA, in *Botany*, from ἐξ ακανθῶν, to be armed with spines; Mart. Mill. *Dict.* v. 2. Billard. *Pl. Syr. fasc.* 1. 10. Willd. *Sp. Pl.* v. 1. 1378. Class and order, *Pentandria Digynia*. Nat. Ord. *Umbellatae*.

Gen. Ch. *General Umbel* of many spreading rays; the inner ones gradually shorter; the innermost extremely short; *partial* of many rays. *General involucre* mostly of 12 channelled leaves, with spinous points; *partial* halved, its intermediate leaf very long, exactly like those of the general *involucre*. *Perianth* scarcely perceptible. *Cor.* uniform,

of five equal, inflexed, heart-shaped petals. *Stam.* Filaments five, longer than the corolla; anthers roundish. *Pistil.* Germen inferior, ovate; styles two, short, straight; stigmas simple. *Fruit* somewhat ovate, striated, separable into two parts. *Seeds* two, ovate, convex and striated on the outside, flat on the inner.

1. *E. heterophylla*. Billard. *Syr. fasc.* 1. t. 2. Gathered by M. La Billardiere near Nazareth. *Root* biennial, tap-shaped. *Stem* two feet, or more in height, slightly zig-zag, branched, round, striated, leafy, smooth. *Leaves* pinnate, smooth; leaflets one or two pair with an odd one; those of the radical leaves ovate, sharply serrated, often cut; those of the stem-leaves lanceolate, acute, narrow, entire, the odd ones very long. *Umbels* terminal, solitary, of about 40 rays; the partial ones of about as many, which are equal and crowded. The *involucral* leaves are very long, prominent, curved downwards, each ending in a sharp spine. *Petals* white. *Anthers* yellowish. This plant is a-kin to the *Echinophora*, (see that article,) but differs generically in the want of a perianth, and in having all the flowers perfect and regular, with naked fruit, not imbedded in the involucre.

EXOCARPUS, from ἐξ, out of, and καρπος, a fruit, because the seed stands naked at the top of a fleshy basis or receptacle resembling a pulpy fruit. Billard. *Voy. Engl. ed.* v. 1. 167. t. 14. Class and order, *Polygamia Monoccia*, or rather, perhaps, *Pentandria Monogynia*. Nat. Ord. *Terebinthaceae*, Juss.

Gen. Ch. *Cal.* Perianth inferior, in five deep roundish, equal segments. *Cor.* none. *Stam.* Filaments five, inserted into the calyx between its segments: anthers small, roundish. *Pistil.* Germen superior, globular; style, short, solitary; stigma peltate, orbicular. *Peric.* none. *Seed* a roundish nut, of one cell, standing on the top of an elliptical, hollow, fleshy receptacle, about thrice its own size. Some flowers have an abortive germen, others have no stamens, all on the same plant.

Ess. Ch. Calyx inferior, in five deep segments. Corolla none. Stamens five. Pistil one. Stigma peltate. Nut of one cell, standing on a hollow fleshy receptacle.

*E. cupressiformis*, the only known species, is an evergreen tree, found in New Holland by M. La Billardiere, as well as by Dr. White. It bears innumerable, compound, pendulous, angular, leafless branches, at whose extremities are situated the minute greenish flowers, produced in the month of May. The fruit is red, not unlike that of the yew in size, form, and colour, but the seed is perfectly exposed to view. This plant has been raised from seed in England, but whether it still remains in the gardens we know not. Its singularity entitles it to notice, and, we believe, it is by no means very tender, if not hardy enough to bear our winters in the open air.

EXOCATACÆLUS, in *Antiquity*, a general denomination, under which were included several grand officers of the church at Constantinople; as, the grand œconomus, grand sacellarius, grand master of the chapel, grand scevophylax, or keeper of the vessels, grand chartophylax, the master of the little chapel, and the protœdicus, or first advocate of the church.

There are many opinions with respect to the etymology of this term. F. Goar apprehends, that all the inferior priests were called Κατακαίλοι, *catacali* q. d. people of a low condition, and that their superiors were called exocatacæli, q. d. people out of the number of catacæli, or above them. Upon the whole, however, he adheres to the sentiment of G. Corelius, who says, that the patriarchal palace, and the apartments of the syncellus, and of the monks in the patriarch's

patriarch's service, were in a very low part of the city which, with regard to the rest, seemed a valley or pit; and that the officers above mentioned had their several houses or palaces έξω, out of the valley; whence the name exocatacæli. M. Du-Cange derives the appellation from their being above the level or rank of the other clerks, and seated at church, &c. in more honourable places erected for that purpose on either side of the patriarch's throne.

The exocatacæli were of great authority: in public assemblies they had the precedence of bishops; and in the patriarchate of Constantinople did the office of deacons, as the cardinals originally did in the church of Rome. Accordingly, in the letter of John IX. to the emperor Basilius Leo, they are called cardinales.

At first they were priests; but some patriarchs of Constantinople, whom Codin does not mention, would have them for the future to be no more than deacons. The reason was, that being priests, each of them had their several churches, wherein they were to officiate on all the grand festival days; so that it unhappily fell out, the patriarch, on the most solemn days, was deserted by all his chief ministers.

EXOC'HAS, or ΕΧΌCΗΕ, from έξω, *without*, and έχω, *to have*, in *Surgery*, a kind of excrescence on the outside of the anus.

EXOCIONITÆ, EXOCIONITES, in *Church Antiquity*. The Arians were first called Exocionites, because, when expelled the city by Theodosius the Great, they retired into a place called Exocionium, and there held their assemblies. Justinian gave the orthodox all the churches of the heretics, excepting that of the Exocionites.

The word is derived from Εξοκίονιον, or Εξοκίονιον, the name of the place above mentioned. Codin, in his *Origines*, says, that the Exocionium was a place encompassed with a wall, built and adorned by Conitantine; and that without the circumference of the wall there was a column, with a statue of that emperor, whence the place took its name, *viz.* from έξω, *without*, and κίον, *column*.

EXOCÆTUS, in *Ichthyology*, a genus of the abdominal kind of fishes; the head is scaly; mouth without teeth; jaws connected at each side; in the gill-membrane ten rays; body whitish; abdomen angulated; pectoral fins large, and formed for flying; anterior part of the rays carinated. These are the flying fishes of English authors.

#### Species.

VOLITANS. Abdomen carinated each side. Linn. *Amœn. Acad.* *Exocætus*, Gronov. *Winged flying fish*, *Donov. Brit. Fishes.*

This is an inhabitant of the American and Red seas, and also those of the warmer parts of Europe: in one or more instances it has been known to appear as far north as Britain. The vastly disproportionate magnitude of the pectoral fins in this genus of fishes affords them extraordinary advantage in effecting their escape when closely pursued by their voracious enemies in the water; but this facility of escape exposes them oftentimes to the attacks of other adversaries, and they not unfrequently elude the pursuit of the bonito, or the porpoise, in their native element, to become the prey of gulls, corvorants, and other aquatic birds that hover over the water to seize on them in their aerial flight. They remain only for a short time suspended in the air before they again dive into the water, and after a pause of a few moments emerge again at some distance. They often quit the water in shoals, and sometimes alight on board ships in great numbers. The flesh is occasionally eaten.

The colour is silvery, with the back rather blueish; the

pectoral fins blueish, edged with yellow; ventral fins and extremity of the tail sometimes reddish.

EXILIENS. Ventral fin reaching to the tail. Gmel. Bloch. *Swallow fish*.

A native of the Mediterranean and Red seas. The colour is silvery, blue on the back, with the fins yellowish at the base, with the extremity blueish. The flesh is in esteem.

MESOGASTER. Ventral fins in the middle of the abdomen. Bloch. *Atlantic flying fish*.

Native of the Atlantic seas, and was observed by Plumier about the coasts of the Antilles. The fish is bright silvery, with the back and fins blueish. The species is sufficiently distinguished by the situation of the ventral fins.

COMMERSONII. Dorsal fin marked with a dark blue spot.

CEPEDE. *Commersonian flying fish*. Shaw *Gen. Zool.*

Described by Commerfon as resembling the first species, except in having a dark blue spot on that part of the dorsal fin nearest the tail, and the ventral fins placed beyond the middle of the abdomen, their tips reaching to about the middle of the anal fin.

The last mentioned species, we are inclined to believe, may not differ specifically from the fish described by Bloch under the name of mesogaster: the evolans and volitans of Linnæus, according to some writers, constitute but one species; and we should also speak with diffidence of the fish denominated exocætus non volitans by Forkal; is it a variety of volitans β; as Gmelin considers, or rather an error arising from some accidental circumstance?

EXOCYSTE, or ΕΧΟCΥCΤΙC, from έξω, *without*, and κύστιC, *the bladder*. Writers define this term of surgery a prolapsus of the lining of the bladder. We are probably to understand by the word, a protrusion of the lining outward, between the fasciculi of the muscular coat of this organ, an occurrence which we know does really sometimes take place. Stones have been found protruded in this manner, carrying along with them a part of the lining of the bladder.

EXODIARY, EXODIARIUS, in the *Ancient Roman Tragedy*, was a droll, or mime, who appeared on the stage when the tragedy was ended, and performed what they called the exodium, or conclusion of the shew, to divert the company.

EXODIUM, Εξοδιον, in the *Ancient Greek Drama*, was one of the four parts or divisions of a tragedy.

The word is formed from the Greek, έξοδοC, *going out*, *digression*, of εξ and οδοC, *way, road*. Festus, lib. v. calls it *exitus*.

The exodium, according to Aristotle, was so much as was rehearsed after the chorus had ceased to sing for the last time; so that exodium with them was far from being what the epilogue is with us, as several people have imagined it was.

The exodium was so much of the piece as included the catastrophe and unravelling of the plot; which catastrophe, &c. in pieces regularly composed, always began after the last singing of the chorus, answering nearly to our fourth and fifth acts. M. Dacier's Comment. on Aristotle's *Poetics*, chap. 12. See *CATASTROPHE* and *CHORUS*.

Among the Romans the exodium was a different thing; it was pretty nearly what farces are with us. After the tragedy was over, came a pantomime on the stage, called the exodiarius, who, by his grimace, jesting, and buffoonery, diverted the people, composed their minds, and wiped away the tears which the tragic spectacle had occasioned to be shed.

Viginere on T. Livy says, the exodium consisted of certain

tain humorous drolling verses, rehearsed by the youth at the end of the fabulæ atellanæ, and answering to our farces. In another place, the same author says, that the exodia were a kind of interludes in the intervals between the acts, partly fable and pleafantry, partly music, &c. to give time both for the fpectators and actors to recover breath. The passage in Livy, whence he takes the notion, is lib. vii. dec. 1. "Ridicula intexta versibus, quæ juvenus inter se more antiquo jactare cœpit, eaque conferta sunt fabulis potissimum atellanis." See also Juvenal.

"Urbicus exodio risum movet Attellanæ  
Gestibus Autonoes."

EXODIUM, in the *Septuagint*, signifies the end or conclusion of a feast.

The Hebrew text calls the day *תַּרְעוּ*, which the Seventy render *Ἐξόδιον*.

In particular, *exodion* is used for the eighth day of the feast of tabernacles, which, it is said, had a special view to the commemoration of the Exodus, or departure out of Egypt, though there is nothing of it expressed in Scripture.

EXODIUM, was also the name of a song sung at the conclusion of a meal or feast.

EXODUS, the second of the five books of Moses.

The word in its original Greek, *Ἐξόδος*, literally imports a going out, or journey; and was applied to this book, because the history of the Israelites' passage out of Egypt is related therein. Besides this, it contains the story of what was transacted in Egypt from the death of Joseph to the delivery of the Jews; as well as what passed in the wilderness, and particularly at mount Sinai, to the building of the tabernacle.

The Hebrews call it *veelle semoth*, q. d. *hæc nomina*, these are the initial words of the book; for the same reason they call Genesis, *beresith*, q. d. *in principio, in the beginning*.

EX OFFICIO, in *Law*, denotes a power which a person has in virtue of his office, to do certain things without being applied to; as a justice of peace may not only grant surety of the peace, at the complaint or request of any person, but he may demand and take it, *ex officio*, at discretion, &c. Dalt. 270.

By a branch of statute, 1 Eliz. the queen, by her letters patent, might authorize any persons exercising ecclesiastical jurisdiction to administer an oath, *ex officio*, whereby supposed offenders were forced to confess, accuse, or clear themselves of any criminal matter, &c. but this branch relating to this oath is repealed by 17 Car. I. cap. 11.

EX OFFICIO *Informations*. See INFORMATION.

EXOLICETUS, in *Natural History*, a name used among the writers of the middle ages to express a small stone which had such a variety of colours that it dazzled, as they say, people's eyes in looking at them. It is said to have been found in Libya. The name is probably only a corruption of the hexacantalithos of Pliny and the older writers; and this seems to have been no other than a name for the opal.

EXOMIS, of *ἐξ, out of*, and *ωμος, shoulder*, in *Antiquity*, a straight narrow garment through which the shoulders appeared. It had something in common with the tunic, and something with the pallium. It was worn by slaves, servants, and the lower classes of people among the Romans.

EXOMOLOGESIS, *Ἐξομολογήσεις*, formed of *Ἐξομολογεῖν, I confess*, a term little used but in speaking of the ancient ceremonies of repentance, whereof the exomologesis, by us called *confession*, was a part.

Some of the ancients, and particularly Tertullian, De

Pœnit. cap. 9. use the word in a greater latitude, as comprehending the whole of repentance.

A public exomologesis was never commanded by the church for secret sins, as may be seen in the capitulars of Charlemagne, and the canons of divers councils.

EXOMPHALIOS, from *ἐξ, out*, and *ομφαλος, the navel*, in *Surgery*, an umbilical hernia, or a disease which consists of a protrusion of some of the abdominal viscera at the navel. The subject will be particularly considered in the article HERNIA.

EXONCHOMA, from *ἐξ, out*, and *ογκος, a tumour*, any large prominent swelling.

EXONEIROISIS, from *ἐξ, out*, and *ονειρος, dream*, a nocturnal pollution or emission of the semen in dreams. This, if it happens but rarely, is usually a sign only of redundant vigour; but if it happens frequently, is a sign of weakness of the seminal vessels, which is most frequently the case.

EXONERATIONE SECTÆ, in *Law*, a writ that lay for the king's ward, to be freed from all suit to the county-court, hundred-court, leet, &c. during the wardship. F. N. B. 158.

EXONYCHOS, of *ἐξ, without*, and *οὐξ, a nail*, in *Botany*, a name given by some of the ancient writers, among whom are Dioscorides and Pliny, to the gromwell or lithospermum. See ÆGONYCHUS.

EXOPHTHALMIA, from *ἐξ, out*, and *ὀφθαλμος, the eye*, in *Surgery*, a disease consisting of a protrusion, or a preternatural projection of the globe of the eye from the orbit, so that the part cannot be duly covered by the eye-lids. The disorder may proceed either from a morbid enlargement of the eye-ball, or what, perhaps, is a still more common cause, some tumour which occupies or diminishes the cavity of the orbit, and consequently displaces the eye.

The affection has several other names besides exophthalmia; as, for instance, bupthalmus, ophthalmoptosis, prolapsum oculi, ecpiemosis, melon, &c.

From the few words already delivered on the subject, it is easy to perceive that exophthalmia may arise from a variety of causes, and must of course require very different modes of treatment in different cases.

One cause of the disorder noticed by writers, is a disease of the fat and cellular substances situated in the orbit, and serving as a support to the eye-ball. In this case the surface of the eye appears more moistened with tears than usual, and the fat and cellular substance becoming thickened and indurated, forces the eye-ball forward out of its socket. As the eye cannot now be properly covered and sheltered by the eye-lids, it inflames, and ulcerates on its surface, and the patient becomes afflicted with very severe and deep-seated pain. This sort of cause is as difficult of removal, when the disease has advanced to a certain extent, as it is difficult of detection at an early period of the case. The famous oculist, Saint Yves, pretends, however, to have sometimes dispersed such thickenings of the cellular substance in the orbit by persevering in the exhibition of calomel and purgative medicines. The same author assures us, that he successfully exhibited the æthiops mineralis to a scrofulous patient for three months, whose eye-ball protruded to the extent of three lines, by reason of a morbid thickening of the cellular substance, and an enlargement of the lachrymal gland.

When the disease does not yield to any remedies, the symptoms may become so urgent as to render the extirpation of the eye indispensably necessary, as is proved by the following case related by Saint Yves. A woman's eye-ball protruded out of its natural situation, in consequence of a morbid thickening of the fat at the bottom of the orbit.

The

## EXOPHTHALMIA.

The disease was attended with insupportable pain, and great restlessness. The symptoms were appeased by the employment of general means, and the progress of the affection was for a time retarded. Three years afterwards, the eye having been left in a projecting condition, Saint Yves was requested to visit the patient. She was now labouring under a violent fever, accompanied with severe head-ach. The globe of the eye was of a leaden colour, and exceedingly prominent, its coats being swollen, and appearing likely to become gangrenous. The medical practitioners who were in the habit of attending the woman were of opinion that the eye ought to be extirpated. The necessity for performing the operation, indeed, seemed to them so urgent, that the proceeding was immediately adopted. The febrile and all untoward symptoms subsided on the fourth or fifth day, and, in about three weeks, the cure was complete.

Exophthalmia may also be occasioned by some tumour of the surrounding parts, either of those within, or of others on the outside of, the orbit. The celebrated French surgeon, M. Louis, met with a man, 40 years of age, in whom a carcinomatous fungus, situated in the antrum, had destroyed the bony plate which constitutes the bottom of the orbit, and pushed the eye-ball almost entirely on the cheek, so as to produce a great deformity of the countenance. The upper jaw bone was carious, both towards the palate and nose, and the patient perished of the afflicting complaints, brought on by the carcinomatous ulceration of all the diseased parts. The exophthalmia was the effect of the prodigious size of the tumour, the growth of which could not be effectually resisted by the bones. The protrusion of the eye, says M. Louis, might have been prevented by attacking the first disease at a proper period, on the side towards the mouth. The growth of the cancerous fungus is represented by this distinguished writer as the effect of a disease of the bone, which latter affection he describes as the consequence of syphilis, which had not been skilfully treated.

Raw makes mention of a child whose left eye was completely protruded from the orbit, and as large as one's two fists. The disease, which had only begun a few months before, proved fatal. On opening the cranium, a fungous swelling was discovered, the base of which was connected with the dura mater above the orbit, without any disease of the cerebrum.

Exophthalmia, however, originates still more frequently from the enlargement of an exostosis, which arises within the orbit, and forces the eye-ball out, in proportion as it increases in magnitude. When the bony swelling is situated near the edge of the orbit, the tumour may be attacked with beneficial effects, without meddling with the eye itself. The truth of what has just now been observed is illustrated by the following case. A woman, 30 years of age, had a fistula lachrymalis, for which she had undergone an operation to no purpose. The bones became enlarged, and, fifteen years afterwards, an exostosis of the os planum and internal angular process of the os frontis had attained the size of an egg. The globe of the eye, being laterally compressed, was forced out of the orbit, and, in some measure, hung over that part of the cheek which was near the lesser angle. M. Brassant applied a caustic to the exostosis; suppuration ensued, and in the course of three or four months an exfoliation of a considerable portion of the bony swelling took place, the eye resumed its natural position, and the cure was completed a short time afterwards.

Exophthalmia is sometimes produced by the formation of a sciatomatous, or schirrous tumour, at the bottom,

or sides of the orbit. Trincavelli, Bonnetus, and Saint-Yves, furnish us with several examples of this sort. Here an operation is requisite; but a great deal of patience and dexterity are essential in its performance. As the recital of facts tends to the elucidation both of precept and practice, we shall offer an abridged account of a case, related by Dr. Hope, in the Philosophical Transactions, where every thing respecting the method of treatment is very perspicuously explained. A young woman, eighteen years of age, was affected, when twelve years old, with a distortion of her left eye, towards the temple. This circumstance arose gradually, in consequence of the growth of a tumour between the eye and the orbit. In a few years, the swelling protruded externally, in the form of a hard tumour, which extended from the greater angle nearly to the lesser one, beneath the lower eyelid, and which reached nearly half an inch over the cheek. This tumour had pushed almost the whole eye-ball out of the orbit, so that the pupil was removed more than three inches from its proper place. The eye was also much more prominent than the other, pushed over the temple, and quite motionless, which circumstances, together with the tumour, presented a frightful appearance. The sight, however, was not lost. Dr Hope, though dissuaded by Monro, undertook the cure of the patient in the year 1744. Having placed her in a convenient posture, and made the integuments tense, he made an incision about an inch long, from the greater to the lesser angle, following the direction of the fibres of the orbicularis palpebrarum muscle. The lips of the wound being separated, he next passed a crooked needle, armed with some silk, through the middle of the tumour, and, regularly as he cut all the adhesions with a bistoury, he drew outward the whole mass of the disease. Scissors were employed for dividing such connections, as were the most deeply situated. The part which was thus cut out appeared to be furnished with a thick membranous substance, exclusively of the body of the tumour, which was of a regular, spherical, smooth form, and about as large as a small pigeon's egg; the interior was of a fleshy structure. In detaching the swelling from its adhesions, several callous indurations were met with, attached to the globe of the eye. The tumour being extirpated, Dr Hope introduced his finger to the bottom of the orbit, where he felt several hardneses and callosities still remaining; he kept his finger there, and having by this means passed in a needle and ligature, he drew them through the base of the callosities. Now having directed an assistant to hold up the ligature, he passed in the point of a pair of scissors, on the end of his finger, and made two or three strokes with them, in the place where he felt the roots of the callous hardneses. Thus he succeeded in cutting away the whole of the indurated parts, so as to leave the bottom of the orbit, as far as he could ascertain, perfectly smooth and free from callosity. All the time that the operation lasted, no hæmorrhage of any consequence took place: only a large quantity of dark-coloured grumous blood was poured out from the varicous vessels. The wound was dressed with some dry lint, which was not removed till the third day. The eyelids and tunica conjunctiva were affected with a slabby kind of swelling, attended with a slight inflammation and pain in the anterior part of the head. The dressings consisted of simple digestive and resolvent applications. The pain in the head, and the tumefaction continued three days, without any formation of matter. Dr. Hope then touched the bottom of the wound with the lapis infernalis, and, a few hours afterwards, a large quantity of black blood was discharged. From this period the pain in the head, and the

## EXOPHTHALMIA.

Swelling subsided; there was also emitted, during the two succeeding days, a bloody sanies, which occurrence induced Dr. Hope to make use of some injections of warm water, mixed with a little spirit of wine, and honey of roses. After the adoption of this plan of treatment, the pus assumed a more favourable appearance. Such soft, fungous excrescences as arose in the course of the cure, were destroyed with the lapis infernalis, and it was not long before the wound was entirely healed. The eye, however, remained unalterably immovable; for the abductor muscles had been so long contracted, while the adductors had been for so considerable a time stretched and tense, that they had completely lost all power of action.

Finding, that by making rather forcible pressure on the eye-ball, the part could be made to return, in a great degree, into the orbit, though it became protruded again as soon as such pressure was discontinued; Dr. Hope conceived, that a bandage which would constantly keep up a graduated compression, might be attended with some benefit, and determine the muscles more speedily to resume their proper tone, by maintaining the eye in its natural situation. Conformably to this idea, this gentleman caused a steel bandage to be constructed, with a concave plate proportioned to the convexity of the globe of the eye. This apparatus made pressure on the side of the eye-ball next the temple, by means of a screw. The machine was put on, after gently pushing back the eye into its natural situation with the hand; and then laying a soft compress between the eye and the plate of copper, Dr. Hope used to make the pressure act on the part by means of the screw, in such a way, that it was impossible for the eye to become displaced outward again, as it usually was before. With the aid of this bandage, which the patient wore constantly, night and day, and which was gradually tightened more and more, the eye regained its natural position in the space of about twenty days, and did not deviate from it again. At the time when the case was published, the eye was capable of motion in every direction, and the patient could see quite as well with it as the other. The wound got completely well in about a month, and only seven weeks elapsed before the cure was, in every respect, perfect.

Respecting the foregoing case, M. Louis observes, that it certainly does honour to the skill and intelligence of the gentleman who undertook the treatment.

Le Dran was equally successful in the treatment of a similar disease, though certainly it was not so considerable as the preceding. The means made use of, were the actual cautery and alternative medicines. The subject was a young lady, aged eighteen, who, from her infancy, had been subject to inflammations about her lips, eyes, and ears. She had had a fistula lachrymalis, and, some time after the usual operation for this complaint, there originated, at the lesser angle of the eye, a fungous excrescence, which protruded from the orbit, and had been successively removed with the knife, and touched with the lapis infernalis; but in vain, as the tumour always made its appearance again. This plan of treatment was not attended with any greater success under the hands of Le Dran, and, consequently, he soon made up his mind to attack the excrescence, by introducing the actual cautery into its centre. For this purpose, he took a long, large, sewing needle, and had it firmly fixed on a handle. The instrument, having been made red-hot in the flame of a wax-candle, was pushed to the depth of about half an inch into the middle of the swelling. By repeating the application of the cautery three or four times, at intervals of a few days, Le Dran succeeded in destroying the tumour as deeply as its root,

the action of the fire having extended beyond the parts actually touched with the heated needle. The consequence was, that the swelling never grew again. To render this cure more certain, Le Dran, for a long while, kept the cauterised part open, and the patient was ordered to take alternative medicines, the chief of which were calomel and aethiops mineralis.

The two foregoing examples prove what surgery can accomplish, when the disease is taken in time. However, when the proper kind of treatment has been deferred too long, the affection of the eye becomes of such a description, as to be irremediable. Nothing now remains to be done except extirpating, not only the tumour, but also the whole of the eye-ball. Even this formidable operation is often impracticable, particularly when the parietes of the orbit are diseased. For the bones, in consequence of the pressure made upon them by the swelling, are rendered carious, and very foul ill-conditioned ulcers are produced. In this state there can be but little hope of a recovery, whatever mode of treatment is adopted.

One species of exophthalmia, which is indeed uncommon, but not the less worthy of being known, is that which is occasioned by an encysted tumour. In the fourth volume of the Medical Observations and Inquiries, there is an instance recorded by Dr. Broclesby. A labouring man of the parish of Haselmere, in Surry, had been for several years afflicted with a pain and an obscurity of sight in one of his eyes. The affection continued, without much attention being paid to it, until, about two or three years afterwards, the man became quite blind on that side. At this period, the globe of the eye was protruded outward in such a manner, that almost the whole of the inner surface of the lower eye-lid was turned out, and hung down over the cheek, so as to form a true ectropium.

Several surgeons who were consulted advised the patient not to expose himself to the risk of an operation, fearful that the disease might be converted into one of a cancerous nature. Notwithstanding this counsel, the man did not cease going about to have the advice of all such persons as seemed likely to afford him any assistance. At length, he applied to Mr. Dale Ingram, who, having carefully examined the disease, thought, that on compressing different places, he felt a decided fluctuation below the globe of the eye. He immediately suspected, that the fluid was contained in a cyst, and, consequently, that the patient might receive relief from an operation. However, the above gentleman would not undertake any thing without consulting Mr. Bromfield.

The latter surgeon, after a careful examination, was not against the probability of success, and he did the operation in the following manner. After having covered the sound eye, by tying a handkerchief round the head, and put the eye-lids of the affected eye as near together as possible, and directed them to be held in this position, Mr. Bromfield made an incision through the lower eye-lid to the conjunctiva, and thus made a sufficient opening for the introduction of his finger behind the globe of the eye. In this way he was enabled to put in a very narrow sharp-pointed knife, for the purpose of puncturing the substance, which was taken to be the cyst. Mr. Bromfield was not deceived in his expectation; for, as soon as the opening was made, nearly a glassful of a thin transparent fluid was discharged. He now waited a little, both in order to give the patient an opportunity of washing out of his mouth some blood, which had got into it, and for the sake of considering what steps could be taken to extirpate the cyst, which had contained the fluid. At last, he determined to proceed as follows: he

passed into the wound a double kind of tenaculum, with which he took hold of the cyst, and then dissected it entirely away. The wound was filled with soft lint, and the dressings were kept on with a suitable bandage.

In less than four and twenty hours there appeared on the same side of the face a considerable degree of swelling, which soon subsided, however, on a dilatation of the first wound being made, lighter dressings being put on, and the bowels opened. In less than a month the man got quite well, and returned to his home with infinite satisfaction. Dr. Broclesby observes, that Mr. Ingram was persuaded, before the operation, that the muscles would draw back the eye-ball into the orbit, and that even some degree of vision might return. The doctor could hardly suppose all this possible; but, having an opportunity of seeing the man, about five months afterwards, he could scarcely recognize him. The eye-lids had recovered their original state, and moved as well as those of the opposite eye. The man also informed Dr. Broclesby, that, for about the last month, he had begun to distinguish with the affected eye light from darkness, and that his power of seeing was becoming greater every day. Dr. Broclesby remarks, that he could not find any case of this kind related by authors, except one very analogous instance, recorded by Saint Yves in his treatise on the diseases of the eyes.

The last kind of exophthalmia which we have to notice, is that which Sauvages has termed *traumatic*. In this sort of case, the eye is so much protruded from the orbit, that surgeons have frequently been induced to remove the displaced part altogether, and this sometimes has been done too inconsiderately for the unfortunate patient. Covillard informs us, in his *Chirurgical Observations*, that he was called to see a man, against whose eye a racket-ball had been struck with such violence, that all the circumference of the globe of the eye was separated from the orbit. A relation of the person who was hurt was standing by with a pair of scissars in his hand, ready to cut the rest of the parts which connected the eye with the head. Covillard entered the room in time, and very fortunately, to resist this proceeding, as a complete cure ensued without having recourse to it. Indeed, such was the success, that the patient's power of seeing suffered no kind of diminution or impairment. A similar instance, though arising from a very different cause, occurred to Mr. Benjamin Bell. The eye was almost knocked out of the orbit by the violence with which a pointed piece of iron had entered betwixt the socket and the eye-ball. The iron had passed through a portion of the orbit, and remained firmly fixed there for about a quarter of an hour. During the whole of this time, the patient suffered insupportable pain. He had completely lost the faculty of seeing, and the eye-ball protruded in such a manner, that there was every reason to fear that the optic nerve was ruptured, and, consequently, great doubt concerning the propriety of replacing the part, or not. However, as a little delay did not seem likely to be dangerous, it was determined to wait a little. On the first removal of the dressings, and after taking away the iron, which could only be done with difficulty, so deeply had it stuck, it was with pleasure and astonishment that the sight was found to return immediately, even before the eye had been replaced. The inflammation which followed was soon appeased by proper remedies, and vision was re-established in its original perfection.

Mr. White makes mention of an analogous example in his book of surgical cases, with this difference, however, that the eye was protruded in a still greater degree.

These two instances confirm the one recorded by Covil-

lard, and weigh against what Maitre Jean has stated, namely, that Covillard's case is not authentic.

In order to conceive the truth of the foregoing observations, we have only to recollect the way in which the eye is retained in, and connected with the orbit. The surface of the boundaries of each orbit (says M. Louis, in defending Covillard's case,) is oblique, and inclines behind more towards the temple than the nose. The eye-ball is fixed on the side towards the nose, and juts out in front beyond the cavity of the orbit. Hence, it is manifest from the slightest examination, that the globe of the eye, in the natural state, is partly situated on the outside of the orbit. When it is also considered that the optic nerve is very loose, in order to be adapted for readily following, without being at all stretched, all the rotatory motions of the eye-ball, produced by the action of the different muscles belonging to this organ, we can then have no difficulty in imagining how the eye may make an immense protrusion outward, in consequence of an inconsiderable swelling, and how it may seem to be quite displaced from its socket, without either the optic nerve or the muscles being torn or lacerated.

**EXORCISM**, Εξορκισμός, prayers or conjurations wherewith to exorcise, *i. e.* to drive out devils or dæmons from persons apprehended to be possessed, or to preserve from danger.

The word is derived from the Greek, εξορκίζω, *adjurare, conjurare, to adjure, or conjure*. In most dictionaries, exorcism and conjuration are used as synonymous; but in reality, conjuration is only a part of the exorcism; and the exorcism the ceremony entire. The conjuration is properly the formula, where the devil is commanded to come forth, &c.

Exorcisms are of great use in the Romish church; their prelates, &c. are frequently exorcising demoniacal persons. The priests make holy water by exorcising common water a certain number of times. In reality, the exorcism is a part in most of their consecrations.

Exorcisms had anciently another and farther purpose; being applied by way of trial or purgation to extort the truth from the accused.

The exorcism, in this sense, was a sort of bread conjured and exorcised for the purpose; and the opinion was, that if the person was criminal he could not swallow the bread.

This, it seems, was a frequent practice in the time of our Edward III. and the bread thus exorcised was said to be cursed.

Linderbroeck gives instances of exorcisms with barley-bread, and others with cheese; and hence, probably, might arise that popular imprecation, "May this bread choak me, if I tell a lye." See **ORDEAL** and **JUDICIUM Dei**.

**EXORCIST**, in the *Romish Church*, a priest, or tonsured clerk, who has received the four lesser orders, one of which is that of exorcist.

The term is likewise applied to a prelate, or to a priest delegated by a prelate, who actually exorcises a person possessed.

It is a dispute among divines whether ever the Greeks had any such order as that of exorcist. Fa. Goar, in his *Notes on the Greek Euchologion*, has made it probable they had, from several concurring passages in St. Dionysius and St. Ignatius Martyr.

The ordination of exorcists is performed in the time of mass, their principal office being to expel devils. The fourth council of Carthage, can. 7. appoints, that in the ordination of exorcists, the bishop, putting the book of ex-

orcisms in their hands, shall say these words: "Receive it, and keep it in remembrance, and have power to lay hands on envergemeni, whether baptised or catechumens; which form still obtains."

M. Fleury mentions certain people among the Jews who travelled round the country, making profession of driving out devils by invocations, which, they pretended, had been taught them by Solomon; these were also called exorcists. See Joseph. Antiq. Jud. lib. viii. cap. Origen. Tract. xxxv. in Matt. 35. 63.

EXORDIUM, in *Oratory*, the preamble or beginning of a discourse or speech, serving to prepare the audience and introduce the matter in hand.

The word is formed from the Latin *ordiri*, to begin, by a metaphor taken from the weavers, who are said, *ordiri telam*, to begin, or *warp* a web, by disposing and ordering the threads in a certain manner for the future work. See *WARP*.

The exordium, on other occasions, is called the *prologue*, *prælude*, and *proem*.

Cicero defines exordium a part of an oration, whereby the minds of the audience are duly prepared for what remains to be said. The exordium is a part of principal importance, and is to be laboured with extraordinary care; whence Tully calls it "difficillima pars orationis."

Cicero and Quintilian mention three ends, to one or other of which it should be subservient; viz. "reddere auditores benevolos, attentos, dociles." The first end, or that of conciliating the good will of the hearers, may be effected by a selection of topics, in causes at the bar, from the particular situation of the speaker himself, or of his client, or from the character and behaviour of his antagonist contrasted with his own; on other occasions, from the nature of the subject, as closely connected with the interest of the hearers; and, in general, from the modesty and good intention with which the speaker enters upon his subject. The second end, or that of exciting and engaging the attention of the hearers, may be accomplished by giving them some hints of the importance, dignity, or novelty of the subject; or some favourable view of the clearness and precision with which it is to be treated, and of the brevity with which it is to be discussed. In order to effect the third end, or to render the hearers docile, or open to persuasion, the speaker must begin with studying to remove any particular prepossessions they may have contracted against the cause, or side of the argument which he espouses.

The ancient critics distinguish two kinds of introduction, which they call "Principium," in which the orator plainly and directly professes his aim in speaking; and "Insinuatio," where, presuming the disposition of the audience to be much against the orator, he must gradually reconcile them to hearing him, before he plainly discovers the point which he has in view. Of this latter sort of introduction we have an admirable specimen in Cicero's second oration against Rullus.

Exordiums are of two kinds; either just and formal, or vehement and abrupt. In the first, the audience is prepared and conducted by due and easy steps; in the second, the orator, as if seized with some sudden passion, breaks out upon his audience at once. Such is that exordium of Isaiah; "Hear, Oh heavens! and give ear, Oh earth!" Or that of Cicero against Catiline; "Quousque tandem abutere patientia nostra, Catilina?" Abrupt exordiums are most suitable on occasions of extraordinary joy, indignation, or the like; though we have instances of panegyrics of the greatest orators, begun abruptly, without any such occasions. Such is that of Gorgias, who began his elege of the

city and people of Elis with *Ἠλίας, ἡ πόλις Ἠλιεύων, Elis, beata civitas*. Abrupt, hasty, exordiums, were more to the taste and manner of the Greeks than of the Latins.

Agreeably to the objects which the orator should have in view in this part of his discourse, as we have already stated them, the requisites in an exordium are, 1. *Propriety*, whereby the exordium appears easy and natural, becomes of a piece with the whole discourse, and matches it as a part does the whole; so that it could not be accommodated to any other, or, perhaps, a contrary occasion. The ancient orators were very defective in this point; their exordiums had frequently nothing in common with the subject.

In order to render introductions natural and easy, Dr. Blair suggests that they should not be planned, till the substance of the discourse has been thoroughly digested in the mind. This mode of forming an introduction is conformable to the rule given by Cicero, though not always to his practice. "Omnibus rebus consideratis," says he, "tum denique id quod primum est dicendum, postremum soleo cogitare, quo utor exordio. Nam si quando id primum invenire volui nullum mihi occurrit, nisi aut exile, aut nugatorium, aut vulgare;" i. e. "when I have planned and digested all the materials of my discourse, it is my custom to think, in the last place, of the introduction with which I am to begin. For if at any time I have endeavoured to invent an introduction first, nothing has ever occurred to me for that purpose, but what was trifling, nugatory, and vulgar."

2. *Modesty*, or an ingenuous bashfulness, which recommends the orator exceedingly to the favour of his audience. This is what Cicero extols so much in L. Crassus, "Fuit enim in L. Crasso pudor quidnam, qui non modo non obesset ejus orationi, sed etiam probitatis commendatione prodesset." The same Tully owns of himself, that at the beginning of his oration every limb trembled, and his whole mind was in a flutter. The vain-glory of that author should be carefully avoided, of whom Horace speaks, and who began his poem "Fortunam Priami cantabo et nobile bellum."

The modesty of the orator should discover itself not only in his expressions at the beginning, but in his whole manner; in his looks, in his gestures, and in the tone of his voice. However, the modesty of an introduction should never betray any thing mean or abject. The orator, whilst he exhibits to his hearers modesty and diffidence, real and not affected, should manifest a becoming sense of dignity, arising from a persuasion of the justice or importance of the subject of which he is to speak. The modesty of an introduction requires that it should not promise too much. "Non fumum ex fulgore, sed ex fumo dare lucem." Horace.

"He does not lavish at a blaze his fire,  
Sudden to glare, and then in smoke expire;  
But rises from a cloud of smoke to light,  
And pours his specious miracles to sight."—Francis.

Although, in general, the orator should not put forth his whole strength in the beginning, but gradually, rise as his discourse advances; yet there are cases in which he may be allowed to set out in a high and bold tone; e. g. when he rises to defend some cause which has been much decried by the public. In subjects too of a declamatory nature, and in sermons, where the subject is striking, a magnificent introduction has sometimes a good effect, if it be properly supported in the sequel. Bossuet, Flechier, and the other celebrated French preachers, very often begin their discourses with laboured and sublime introductions; these raise attention, and throw a lustre on the subject; but every speaker should be on his guard against striking a higher note

at the beginning than he is able to keep up in his progress, and thus disappointing the expectations which he has excited. Among English preachers, attempts of this kind are not always so successful. Variety should be studied in introductions as much as possible. Explanatory introductions from the context are the most simple of any, and frequently the best that can be used; but they should never be long. An historical introduction has generally a happy effect in rousing attention; when one can lay hold upon some noted fact that is connected with the text or discourse, and by a proper illustration of it, open the way to the subject that is to be treated of.

3. *Brevity*. not amplified or swelled with a detail of circumstances, or a long circuit of words; and in this respect it should be accommodated to the length of the discourse; nor should the introduction anticipate any material part of the subject.

4. The *style* of the exordium should be just, easy, and pleasant. Quintilian facetiously compares a faulty exordium to a scarred face, which is presently discerned, and very disagreeable. Thus, Cicero, "Vestibula, aditusque ad causam facias illustres."

Correctness of expression is peculiarly requisite on account of the situation of the hearers, who are then more disposed to criticize than in any other stage of the oration or discourse; because they are as yet unoccupied with the subject or the arguments, and their attention is chiefly, if not wholly, directed to the speaker's style and manner. A correct plainness, an elegant simplicity, is the proper character of an introduction; "ut videamur," says Quintilian, "accuratè non callidè dicere."

5. *Calmness* of manner is peculiarly suitable to the exordium. This is seldom the place for vehemence and passion. Emotions must rise as the discourse advances. The minds of the hearers must be prepared, before the speaker can venture on strong and passionate sentiments. To this rule there are some exceptions, as, for instance, when the subject is such that the mere mention of it naturally awakens some passionate emotion, or when the unexpected presence of some person or object, in a popular assembly, inflames the speaker, and makes him break forth with unusual warmth. Either of these will justify what is called the exordium *ab abrupto*. An instance of this kind we have already referred to in Cicero's first oration against Catiline. However, introductions of this kind should rarely occur. In the introduction the speaker should prepare the way for those warm emotions, which he designs to raise in the subsequent parts of his discourse.

The exordium appears an essential part of an oration; though anciently in the Areopagus, Julius Pollux tells us they spoke without any exordium, and passions, and any peroration or epilogue. The like is said to have been done by Xenophon, who began thus: "Darius et Parisatis duos habuere filios."

EXORMISTOS, in *Ichthyology*, a name given by some of the old writers to that species of the petromyzon which other authors call the lampetra fluviatilis, and we in English the lampern. This is distinguished by Ardedi by the name of the petromyzon, with only one series of small teeth in the verge of the mouth, and some large ones, below. See MUSTELA, LAMPETRA, and PETROMYZON.

EXOS, the name by which Rondeletius distinguishes the acipenser huso. See STURGEON.

EXOSTOSIS, from εξ, *out of*, and οστεον, *a bone*. This term, in *Surgery*, signifies an osseous tumour growing on a bone. Also, a swelling of the bone itself.

Boyer remarks, that a swelling may take place in bones

as well as other parts of the body. The particular kind of tumour which occasionally forms on the surface of the bones, is that to which this writer assigns the appellation of *exostosis*. He notices, however, that this name comprehends different species, which should be considered in a distinct manner. Thus, *osteosarcoma* is one peculiar affection; and there is another species of exostosis, different from all others, and which consists principally in a thickening of the periosteum. Boyer is of opinion, that the disease might be very properly named *periostosis*.

In cases of exostosis, the bony swelling acquires, on some occasions, such a degree of hardness, that no vestiges of a fibrous texture can be discerned, and it absolutely resembles ivory. In some instances, the structure of the tumour is spongy; and in others the swelling is composed of a mass of fleshy and bony matter blended together.

According to Boyer, the bones most frequently affected with exostosis are the broad bones of the head, the lower jaw, sternum, humerus, radius, cubitus, the bones of the carpus, and the femur, and tibia. However, he remarks, that there is bone, which may not become the seat of the disease, and the affection may extend to a small, or a considerable portion of it. It is not uncommon to find the bones of the cranium affected with exostosis over their whole extent; and Boyer instances the ossa parietalia, as sometimes acquiring an inch in thickness, in consequence of the affection.

In the majority of cases, an exostosis rises from the surface of a bone, and appears in the form of a hard round tumour. It sometimes occurs near the extremities of the long bones, and, at other times, near the middle portion. It is remarked, that exostoses, originating from a venereal cause, and commonly called *nodes*, are found, for the most part, on compact bones, and such of these as are not thickly covered with soft parts, as, for instance, the bones of the cranium and face, the internal side of the tibia, &c.

Mr. John Bell has treated of tumours of the bones in the third volume of his *Principles of Surgery*. The following extract will serve to shew some of this gentleman's opinions upon the subject: "Many things conspire (says this author) to give the tumour proceeding from a bone a peculiar aspect; it is always irregular and anomalous, never simple. I have rarely seen a single bony protuberance arising from the head, or shaft, of a single bone. When a bone falls into disease, a large proportion of tendinous and muscular parts of bursæ, and of cellular substance partake of the morbid action. The bone lies in the centre of the limb, connected by its larger head with a joint, and by its periosteum with the tendons, bursæ, and muscles; and all this mass of parts is, sooner or later, affected; and since every deposition from vessels appointed for the secretions of bone is solid, and every increase of such a tumour permanent, it soon attains a great size; it is ponderous and massive from the proportion of bony secretion, and from the various structure of these several parts, it has every irregularity of form and substance.

"When the tumour of a bone has attained a considerable size, much of the original structure is destroyed, and a new irregular mass of gelatinous and bony matter is substituted for it. The bony tumour is firm, bulky, and ponderous, but not solid; feeling it from without, we can conjecture of what substance it is composed within; we are sensible that the tumour is covered by a shell, bony in most parts of its circumference, cartilaginous in some parts, and, throughout the whole, yielding and elastic; we are sensible, also, that within there are irregular points, or spiculae traversing the cavities, or cells, of the hollow tumour; that these are mixed with the cartilaginous substance, and with irregular collections

## EXOSTOSIS.

of matter, partly purulent, but chiefly gelatinous; we are sensible of such soft cartilaginous and gelatinous parts being successively added, in the progress of its growth to the tumour, which was, at the first, solid and firm; and we find at last, by pain and partial ulcerations, and by the increase of fluctuation and redness at particular points, that ulceration, the last stage of the disease, approaches. Then the limb is effectually ruined, and the patient must submit to amputation, or die of hectic.

“When such tumour is dissected, we find our suspicions of its internal structure confirmed; we see that foul matter flow out, when we open into the centre of the tumour, which we felt but indistinctly through its walls; the parts which appeared the most solid are hollowed out by ulceration, and full of foul and putrid sanies; while the bone has been declining into disease, the cancelli and marrow have been degenerating into a sort of fatty mass, with which much of the cavity of the tumour is filled, and thence such disease has been very generally described under the name of *osteosteoma*. This fatty excretion, occupying the diseased cavity, is the part which, when the tumour bursts into an open ulcer, throws out such prolific fungus, growing apparently from the substance of the bone, and sprouting up, when amputated, in the course of a few hours. The solid bone, whether radius, or thigh-bone, is annihilated, and a mere shell of osseous matter substituted in its place, and that in a manner so peculiar, that it must seem to the unintelligent observer as if the small and solid bone had been expanded into an extensive and flat plate of osseous substance, whereas the process is in truth very simple and very intelligible. The bone dies piecemeal of ulceration, what, in technical language, is termed caries, and is conveyed away by absorption; but the bone being dead, the surrounding membranes, *viz.* the periosteum and tendinous expansions, which once formed a part of its system of circulation, continue still alive and ready to secrete new bone; and thus it happens, that while a carious abscess preserves a large cavity full of foul matter, the surrounding membranes continue secreting bone, which, like a shell, thin and expanded, covers this cavity, and forms the walls of the tumour, of which some part is composed of thin expanded bone, resembling a cranium, some of cartilage, some of thickened membrane; and this shell is formed in proportion as the original fabric of the bone is destroyed.

“Bone is destroyed by this internal ulceration, just as it is by open caries, piecemeal; the process would not be ulceration, if, while one part were perishing, the other were not active and secreting new matter; so vigorous still is the general life of the bone, while the internal parts are thus suffering, that while one side is wasting with ulcer, the other side is often secreting bone irregularly and profusely, and shooting out into fantastic forms among the membranes and surrounding soft parts, whence the centre of the tumour is cavernous and cellular, and the walls often rough with spinous and projecting points. So merely local is the action of arteries in a tumour, whether osseous or soft, that one side, or part, or bump of a tumour, grows visibly and protrudes; the features and external form of the tumour gradually changing, without any sensible cause; and so peculiar is the secretion of each species of vascular structure, according to the original destination of the part, that in one part of the tumour is generated bone, in another gristle, in another gelatinous effusion; while in another part, the vascular action is violent and destructive, and the solid bone, marrow, and surrounding membranes, are all resolved into a foul and fetid suppuration. From the periosteum is secreted bone: from the marrow, this steatomatous and solid fat, with which much of the

tumour is filled; to the tendinous and aponeurotic parts we can distinctly trace the cartilaginous secretion; and the gelatinous effusions, we can perceive, even during life, have their walls thicker, or thinner, according to the degree of inflammation.

“These are the external characters and internal conditions of a tumour occupying any of the bones. Such tumour arises often from a bruise, or fracture; sometimes from a less obvious cause, or from internal disease. The radius, for example, is fractured at the wrist, re-unites and heals; but heals clumsily, the thickening never subsides, the pain never ceases, and, though not great, is greater than what is natural to a fracture. At length, a sensible tumour arises; at first it is firm, but in proportion as it increases in size, it becomes somewhat soft and elastic, the thin plate of bone, of which it is composed, yielding to the distention from within. From time to time the tumour changes its form, still increasing in bulk. On the side of the radius, it is firm and solid; it bends and yields at the parts most distant from it; it is plainly bony at its basis, and as obviously cartilaginous in the extreme part of its circle; it plainly contains matter in those softer parts, where it yields to the impression of the finger. Cartilaginous knobs arise, and sometimes are reddened on the surface; and, at certain points, the fluctuation is of such a kind, as to imply that the effusion is in part of a gelatinous nature. Thus the tumour grows and extends, with various irregularities in form and consistence; it overhangs the dwindled hand, the use of the joint is lost, and the patient, who might gladly have been delivered of it at an earlier period, has, in the end, no choice left; for, when once it bursts into carious ulceration, it never heals, the fetor is inconceivably overbearing, attended with hectic. You are also to remark, that, when such disease takes place in the hand itself, the joints of each of the fingers grow out into tumours, at first of a heart-like form, corresponding with the articulations of the finger bones; but, in process of time, they grow to globular, irregular, and almost transparent tumours, still firm, or, at least, of a cartilaginous firmness. The whole hand degenerates into a deformed mass, discoloured, ulcerated, and fetid; from the individual knobs of which deformed mass, the points of the respective fingers project like griffin's claws, with crooked nails of enormous length.” Page 58—60.

The foregoing passage makes us tolerably well acquainted with Mr. John Bell's sentiments relative to the pathology of exostoses, and though we do not ourselves adopt some of his conclusions, nor think that all bony tumours coincide with his account, yet many cases certainly answer the description which he has given.

Some exostoses cannot be discovered before the patient's death. Such was the case referred to by Boyer, of a person whose parietal bone was found after death to be three times thicker than natural. A similar case is also related in the memoirs of the academy of Dijon. In the latter example, the patient died from an exostosis on the internal side of the os pubis. The tumour, by pressing on the neck of the bladder, prevented the passage of the urine, and the introduction of the catheter.

Boyer notices the possibility of mistaking the head of a luxated bone for an exostosis. He informs us, that this happened with a young man, whose clavicle was dislocated at the end, which is articulated with the sternum. The tumour, formed by the end of the displaced bone, was mistaken for an exostosis, and was treated as such, of course, with no benefit.

Boyer also adverts to the liability of mistaking the enlargements

## EXOSTOSIS.

enlargements of the ends of ricketty bones for exostoses. Fungous excrescences of the dura mater might likewise (as the same author explains) be erroneously conceived to be exostoses; for, after they have destroyed a part of the bones of the cranium, they form an external protrusion. Their real nature, however, may be easily discriminated by attending to their consistence and progress, and particularly their pulsatory motion, which corresponds with the action of the arteries in general. We need not here say more concerning these swellings, as they are already described in another part of this Cyclopædia. See DURA MATER, *Tumours of*.

There are certain symptoms which may be said to be common to all exostoses; such are, a swelling; a sense of weight; pain, or at least a degree of uneasiness arising from the morbid action; and deformity.

Another class of symptoms may be called *particular*, because they are entirely dependent on the situation of the tumour. Thus, as Boyer observes, and as we have related in the article EXOPHTHALMIA, if an exostosis were to take place in the orbit, the eye would necessarily be expelled from that cavity. An exostosis arising from the inner surface of the clavicle, or sternum, might occasion pressure of considerable blood-vessels, and on the thoracic viscera, so as to induce a train of very dangerous and even fatal consequences.

An exostosis, arising from the internal side of the os pubis, may give rise to a fatal retention of urine, as, indeed, we have already detailed. A similar tumour, similarly situated, might also render parturition, in the natural way, impossible.

The generality of surgical writers represent scrofula as being a cause of exostoses. This statement, however, seems to rest on no foundation whatever. The swelling of the joints, when they are affected with scrofulous disease, is not produced by an expansion of the bones themselves, but altogether by a thickening of the soft parts, sometimes conjoined with a collection of a fluid resembling glair, or of purulent matter in the capsular ligament. The head of a bone, really enlarged from scrofula, has never yet been demonstrated, and cannot be found in any of the collections of morbid preparations in the various museums. The particular form of disease, with which scrofula affects the bones, we shall describe in speaking of the *White Swelling*.

A scorbutic diathesis is also set down by authors as sometimes exciting the growth of exostoses: on this point, we can only profess our ignorance of any rational evidence in favour of the opinion.

The venereal disease does undoubtedly occasion one sort of exostoses, denominated *nodes*; but, these we shall dismiss from present consideration.

It is painful for us to be obliged to acknowledge, that we are almost in total ignorance, in regard to the causes of exostoses; for, excepting contusions and fractures, which sometimes unquestionably lead to the production of bony tumours, we have no certain knowledge of any others.

Mr. John Bell informs us, that he has seen a woman's ankle fall into this disease, in consequence of a very trivial accident; the tibia and fibula grew into a common tumour, the bones seemed annihilated, and a large osseous shell appeared to be substituted in their place. In the course of the disease, the leg became twisted round in a singular manner, and enlarged to the size of a pillow of a settee. The woman died of hectic from the open caries of the tumour. The same author remarks, that the wrist, which is more exposed to sprains and fractures, is most liable to be thus deformed and ruined. He represents the hand

itself as being also particularly subject to similar disorder. The original injury is some slight blow, or sprain; one finger is first deformed; joint after joint enlarges; one finger after another becomes crooked; the nails project like talons, and force their way into the very flesh of the swelled and ulcerated hand, which, according to Mr. John Bell, they sometimes penetrate through and through. At length, the hand degenerates into an unwieldy and irregular mass, studded with knobs and bony tumours. This surgeon tells us, also, that in consequence of a neglected fracture of the collar-bone, in a stout young man, he once saw a tumour produced; partly consisting of bone, and partly of cartilage, rising to the height of six inches, of round figure, and insulated, moving when the arm was moved, too large and too critically situated over the axillary artery, to admit of extirpation, and which Mr. John Bell doubts not has by this time become curious, and occasioned death.

When exostoses originate from external violence, the exciting cause is involved in no obscurity; but the causes in most other instances seem to baffle all human research. Frequently, a constitutional disposition to the formation of bony tumours, in various parts of the body, seems to prevail. Mr. Samuel Cooper, in his "Dictionary of Practical Surgery," quotes an example of a boy, who came out of Cornwall, so excessively afflicted with an apparent propensity to exostoses, or an exuberant deposition of bony matter, that a very trifling blow would occasion a bony swelling on any bone of his body. The ligamentum nuchæ was ossified, and prevented the motion of his neck; the margins of the axillæ were also converted into bone, so that the poor lad was, as it were, completely pinioned.

There is one species of exostosis remaining to be noticed, which is of a very peculiar kind, as it is in its appearance exceedingly like a bony fungus.

A striking instance of such a disease has been recorded by Mr. Abernethy. The case being highly interesting, we shall take the liberty of quoting it. The patient, who was 34 years of age when the account was written, perceived, when about ten years old, a small tumour on his left cheek, which gradually attained the size of a walnut, and then remained for some time stationary. About a year afterwards, the tumour having again enlarged, a caustic was applied to the integuments, so as to expose the bone. The actual cautery was next applied, and an opening thus made into the antrum. After the exfoliation, the antrum became filled with a fungus, which rose out upon the cheek, and could not be restrained by any applications. Part of the fungus also made its way into the mouth, through the socket of the second tricuspid tooth, the other teeth remaining natural. The disease continued in this state nine years, occasionally bleeding in an alarming way. When the patient was in his 20th year, the whole fungus sloughed away during a fever, and did not return. After this, the sides of the aperture in the bone began to grow outwards, forming an exostosis, which grew to a great magnitude. A small exostosis took place in the mouth, but became no larger than a horse-bean. The exostosis of the maxillary bone was of an irregular figure, and projected from the whole circumference of the aperture a great way directly forward. Mr. Abernethy compares its appearance, when he was writing, with that of a large tea-cup fastened upon the face, the bottom of which may be supposed to communicate with the antrum. The diameter of the cup, formed by the circular edge of the bone, was three inches and a half: the depth two inches and seven-eighths. The general height of the sides of the exostosis, from the basis of the face, was two inches; its walls were not thick, and terminated in a thin circular edge. The integuments,

teguments, as they approached this edge, became extenuated, and they extended over the edge into the cavity. The exostosis reached to the nose in front, and to the masseter muscle behind; above it included the very ridge of the orbit, and below it grew from the edge of the alveolar process. A line that would have separated the diseased from the sound bone, would have included the orbit and nose, and indeed one half of the face. Mr. Abernethy saw no means of affording the man relief. *Med. Chirg. Transf.* vol. 2.

In regard to the treatment of exostoses, it is exceedingly difficult to lay down any determinate rules. With the exception of venereal nodes, we cannot say that we are acquainted with any remedy which has the power of diminishing bony tumours. Perhaps blisters kept for a long while open, by means of the savin cerate, and applied to the nearest surface of the integuments, might have the effect of exciting the action of the absorbents, so that the deposited bony matter would be at least in part removed. That blisters would operate in this manner, we may conclude from their having been known to diminish the swelling of venereal nodes, after mercury has ceased to be productive of any benefit. However, we do not mean to represent this plan as likely to answer fully in practice; for, even were it to prove successful, it could only be after such time and perseverance as few patients would allot.

The chief method of getting rid of an exostosis is by attacking the tumour with a cutting instrument, and it is obvious that this mode of proceeding cannot be adopted, except when no anatomical considerations forbid it. Hopes of its success, also, should never be sanguine; because, though you may succeed in removing every particle of the bony swelling, still the deposition of bone may continue, and the disease recur, and this even in a more malignant form.

When an exostosis has acquired much magnitude, it seldom admits of being cut, or sawn away. But there are exceptions to this remark; for Heister records an example of an exostosis, situated on the middle of the sternum, and as large as a child's head, being successfully extirpated. If an exostosis were to be met with, growing on the middle part of one of the long cylindrical bones, with rather a narrow base, an attempt might be prudently made to remove the tumour, notwithstanding its size might be very great. When the attachment of the swelling is on the head of a bone, near a large joint, an endeavour to extirpate the disease is much more dangerous.

It would be in vain to pretend to detail particularly how the operator is to conduct himself in extirpating exostoses. His first object should be, if possible, to make such incisions through the soft parts as will expose the base of the tumour, so as to allow the saw to be applied to it. When this can be effected, it is manifest that the whole of the swelling may be removed by one section made with the saw. In the majority of cases, small short saws with long handles, in a word, the instruments described in Mr. Hey's "*Practical Observations in Surgery*," will be found much more proper and convenient than larger ones.

Sometimes, when owing to depth of situation, or some other anatomical reason, no direct attempt to cut through the base of an exostosis can be made, the surgeon may venture to remove the tumour by attacking its surface with trephines, the saws described by Hey, or with a gouge and mallet, as the French surgeons are so much in the habit of doing. When the consistence of the exostosis is not too hard, a strong knife may be occasionally employed for removing portions of the swelling, which purpose it will accomplish better than any saw.

The ancients, indeed, we might say several of the moderns, have attempted to destroy exostoses with the actual and potential cautery. Sometimes these violent means have fulfilled the object in view; but, frequently, instead of affording relief, they have killed a large portion of the bone, and converted the disease into the more afflicting one of necrosis, attended with large sores and abscesses, and often with such debility and hectic symptoms, as have ended in death.

Few good practitioners of the present day, in England, ever have recourse to this plan for the extirpation of exostoses.

When prudence prohibits an endeavour to cut away an exostosis, the disease should never be suffered to expand itself in so great a degree as to deprive the patient of the choice of parting with his limb for the preservation of his life. Amputation should always be performed ere the disorder attains this deplorable state.

We shall conclude the present article with this general observation, that if an attempt is to be made to extirpate an exostosis, let it be done at an early period of the disease, before its size is very considerable.

EXOSTRA, in the *Ancient Theatre*, a place where such parts of the play were recited as were supposed to be acted privately in the house.

EXOSTRA was likewise the name of a warlike engine used in the sieges of towns.

EXOTERIC and ESOTERIC, are terms denoting *external* and *internal*, and applied to the double doctrine of the ancient philosophers: the one was public or exoteric, the other secret, acroamatic, or esoteric. The first was that which they openly professed and taught to the world; the latter was confined to a small number of chosen disciples. This method was derived originally from the Egyptians, who, according to the united testimony of Herodotus, Diodorus Siculus, Strabo, Plutarch, &c. had a two-fold philosophy, one secret and sacred, another public and common. The same practice also obtained among the Persian Magi, the Druids of the Gauls, and the Brachmans of India. The Egyptian priests, with whom it originated, sustained the character of judges and magistrates, and probably introduced this distinction with a view to the public welfare, and to serve the purposes of legislation and government. Clement of Alexandria informs us, that they communicated their mysteries principally to those who were concerned in the administration of the state; and Plutarch confirms the same declaration. However, others have supposed that they invented the fables of their gods and heroes, and the other external ceremonies of their religion, to disguise and conceal natural and moral truths; but whatever was the motive of their practice, it was certainly applied to political purposes. See ARISTOTLE.

EXOTIC, Εξωτικός, a term properly signifying *foreign*, or *extraneous*, *i. e.* brought from a remote or strange country. In which sense we sometimes say, *exotic*, or *barbarous terms* or *words*, &c.

The word is derived from the Greek, ἐξω, ἐξωθεν, *extra*, *without*, *on the outside*.

EXOTIC is chiefly applied to plants which are natives of foreign countries, particularly those brought from the East and West Indies, and which do not naturally grow in Europe.

The generality of exotics, or exotic plants, do not thrive in England without some peculiar care and culture; they require the warmth of their own climates, whence the use of hot-beds, glass-frames, green-houses, &c. See GREENHOUSE and STOVE.

In sending plants from one country to another, particular cautions are necessary. The plants sent from a hotter country to a colder, should be always put on board in the spring of the year, that the heat of the season may be advancing as they approach the colder climates; and on the contrary, those which are sent from a colder country to a hotter, should be sent in the beginning of winter.

The best way of packing up plants for a voyage, if they be such as will not bear keeping out of the earth, is to have boxes with handles, filling them with earth, and planting the roots as close together as may be; the plants should be set in these boxes three weeks before they are to be put on board; and in good weather they should be set upon the deck, and in bad removed, or covered with a tarpaulin.

If they are going from a hotter country to a cold one, they must have very little moisture; if, on the contrary, they are going from a colder to a warmer, they may be allowed water more largely, and being shaded from the heat of the sun, they will come safe.

Many plants, however, will live out of the earth a great while; as the sedums, euphorbiums, ficoides, and other succulent ones. These need no other care than the packing of them up with moss in a close box, and there should be a little hay put between them, to prevent them from wounding or bruising one another, and holes bored in the boxes to keep them from heating and putrefying. In this manner they will come safe from a voyage of two or three, or even four or five months.

Several trees also will come safely in the same manner, taking them up at a season when they have done growing, and packing them up with moss. Of this sort are oranges, olives, capers, jasmines, and pomegranate-trees. These, and many others, are annually brought over thus from Italy; and though they are three or four months in the passage, seldom miscarry. And the best way of sending over seeds is in their natural husks, in a bag, or packed up in a gourd-shell, keeping them dry, and out of the way of vermin. Miller.

Dr. Lister has a discourse in the *Philosoph. Trans.* on Exotic Diseases, *i. e.* such diseases as are never bred among us, but brought, from time to time, by infection from other countries. Such, according to this author, are, 1. The plague, which is properly a disease of Asia, where it is epidemic. 2. The small-pox, which is an Oriental disease, and not known to Europe, or even Asia Minor or Africa, till a spice-trade was opened to the remotest part of the Indies, whence it originally came, and where it still rages more cruelly than among us. 3. The griping of the guts, which he takes for a disease peculiar to the West Indies, and yearly received from thence: for this, he adds, is a quite different disease from the tormina ventris of the ancients, and is scarce ever known in the midland counties, or far in the north of England.

EXOUCONTII, in *Church History*, a kind of Arian heretics, who maintained that the Son of God was made out of nothing: *i. e.* Ἐκ τῶν ἐκ οὐκέν, supposed by Gothofred to be the same with the Exocionitæ; but this opinion is contradicted by the authority of Theodoret.

EXPAND, in a *Military Sense*, relates to the exterior of a line or front, either for the purpose of occupying a greater space, or in order to outflank the enemy, thereby to beat in his wings upon his centre.

It is often of the greatest importance to present a more extended line of fire, especially if it can be directed towards any particular spot; for instance, when a column is issuing from a defile, a detroit, or pass, the enemy will certainly

endeavour to pour upon its front as heavy a fire as the space may allow,

Thus, he will probably oppose a formidable cannonade thereto, so that the shots may range along the column, doing great havoc therein, not only among the soldiery, but destroying the cattle, and disabling the artillery. The rest of the field he will generally occupy in an infected form, presenting a crescent; much the same as that opposed to the immortal Nelson in his last victory! By this means every musket becomes obnoxious, each being levelled at the head of the column.

If we imagine 3000 men to be drawn up in such a manner as may produce this effect, and that five or six guns are brought to bear as above described, with perhaps a body of cavalry ready to charge in flank, when the column may have proceeded to contend with the centre of the opposing force, we shall then see how necessary it is for the column to expand with all possible celerity, and not to attempt such an attack before a sufficient front can be formed to make it with effect.

The mode of expanding may be seen under the article DEPLOY, where this particular operation will be found more fully described. We shall in this place remark, that expansion is by no means proper where the enemy can bring a large body of cavalry to act in an open country, unless an equal number of such troops may be at hand to oppose them.

Where a line of intrenchments is to be carried, expansion is not eligible; yet the concentration must be managed with peculiar care whenever the enemy may be able to line their works with artillery, especially howitzers of large calibre, which, by pouring grape among close bodies of men, would soon thin their ranks, and probably occasion, what is delicately called, "a precipitate retreat." The best authorities instruct us to say, that nine battles in ten are lost by allowing the troops to be too expanded: in such a condition they are every where weak; whereas, when properly concentrated, they are every where formidable.

We may from this collect, that allowing an army to cover too great an expanse, is, generally speaking, exposing it to ruin; it enables the enemy to force a line in whichever quarter they may judge proper, and, after forcing it, to cut up the several parts in detail. Hence, blockades are, with few exceptions, extremely dangerous, as may be better understood by reference to *environ*, which see.

When a column is to expand or deploy, or when an augmentation of front is to be made, such ought to be done with great promptness, and under a heavy fire from each division, so fast as it can arrive at its station in the line. By this means, especially if the wind be favourable, the whole may be done under cover of the smoke, and the enemy may be so rapidly gained upon, as in turn to render it necessary for him to change position; but without great coolness and firmness, nothing will be effected.

EXPANDING RIGGER, or *Drum*, in *Mechanics*, is a wheel, or rigger, to receive an endless rope, which can be enlarged or diminished in its diameter, to give a greater or less velocity to the rope.

The common expanding rigger is a cast-iron wheel with twelve arms, in each of which a groove is formed, extending nearly from the centre to the circumference, as *AA*, *fig. 5. Plate XXVI. Mechanics*. Against each arm a piece of wood is placed, which has a rebate fitting into the groove, and a screw-bolt passing through both wood and the arm of the wheel; a nut screwed upon the bolt fastens the bolt and wood at any place in the groove: each piece of wood has a groove in it to receive the rope which passes round the

wheel. The diameter of this rigger can be altered by loosening the nuts, then placing the pieces of wood all in one circle of the proposed diameter, and fastening them there by the nuts. To facilitate the placing of the pieces of wood in one circle, each arm is divided into inches, and numbered from the centre.

Mr. Andrew Flint, of London, lately received a premium of fifty guineas from the Society of Arts, for two expanding band wheels, or riggers. *Figs. 5, 6, and 7*, are different views of the first of these; *A A* is a cast metal wheel with twelve arms, each divided by a groove from near the centre to the circumference: these grooves receive rebates on the backs of twelve racks *a a*, *figs. 6 and 7*, which have projecting pieces *b, b*, with grooves to contain the endless rope *d d*. In *fig. 5*, which is a back view of the wheel *ee*, are nuts, which draw up the racks to slide in the grooves without shake, yet freely to and from the centre: the racks are moved all together by means of a circular plate *dd*, which has a spiral rib upon it entering between the teeth of each rack, so that when the plate is turned round, all the racks move to or from the centre at once: the spiral plate *dd* is screwed to an iron cross, which fits upon the axis *ff*, and is turned round by a pinion *g* of six teeth, working into a ring of teeth made in the inside of the spiral plate *d*.

Another method of accomplishing the same object is by means of twelve screws *h* (*figs. 8. and 9*) pointing to the centre of the wheel; they are all moved together by means of equal bevelled wheels fixed on them; by this means the screws are turned about contrary ways alternately: they must, therefore, be alternately cut right handed and left handed, that they may produce the same effect. The screws are turned, when the diameter of the rigger is to be altered, by a winch put upon any of the three squares *h, h, h*, on the ends of the screws. In this machine the number of screws must be even.

*Figs. 10, 11, and 12*, are drawings of an expanding rigger contrived by the writer of this article: it consists of two wheels of cast-iron *A, A*, (*figs. 10, 11, and 12*.) which have sixteen sectorial apertures marked *a*, which leave sixteen arms between them; the arms and the spaces are exactly equal, and each arm has a triangular piece of wood *b d e*, (*fig. 12*.) screwed upon it, by four screws going through the arm into the wood, which is also kept firm and perpendicular to the face of the wheel, by a rib *f*, (*fig. 11*.) which projects from each arm, and is let into a groove cut in the wood. The wheels have sockets *g, g*, (*figs. 10 and 12*.) which are bored out with a very true cylindrical hole to receive the shaft or spindle *B B* of the rigger, which is turned in the lathe to fit the sockets without shake, yet at the same time allowing them to move backwards and forwards upon the axis *B B*. The wheels are put together upon the spindle facing each other, the wooden triangles of one wheel entering the space between the arms of the other, as is shewn in *figs. 10 and 12*; in this manner it is plain that the points, or rather plane, of intersection of the triangles *b d e* of each wheel, will form a circular groove to receive a rope, which groove can be increased in its diameter by advancing the wheels towards each other, or diminished by setting them farther apart, as in *fig. 10*. The wheels are prevented from turning on the spindle by means of a fillet, which is inserted partly into a groove cut in the axis, and partly in another groove made in the socket of the wheel. The wheels may be brought nearer together, or thrown farther apart, by two screws *h, h*, (*fig. 12*.) which have sockets in one wheel, and are tapped into the other: two equal cog-wheels *i, i*, are keyed fast upon the screws, and an intermediate cog-wheel *k*, placed loosely upon the main axis

between them, causes both screws to turn at the same time. A more simple method of altering the diameter is by pushing the wheels together by hand, and fastening them to the axis by screws *e, e*, *fig. 10*.

EXPANSION, in *Metaphysics*, expresses the idea we have of lasting or preserving distance, *i. e.* of distance, all the parts whereof exist together.

EXPANSION, from the Latin *expando*, in *Philosophy*, denotes the increment of surface or of bulk, of which natural bodies are susceptible. With respect to the expansion of surface, see the articles DUCTILITY and GOLD *Beating*.

Bodies of every kind, as far as we are acquainted with them, are expanded in bulk by heat, and are contracted by cold; and to this law there are very few exceptions, which will be noticed in due time. The expansions, or the increments of bulk, are not exactly proportional to the increments of heat in the same body; nor are different bodies expanded alike by the like elevation of temperature. Thus, if a quantity of water be increased one inch in bulk, by the communication of ten degrees of heat, the communication of twice or thrice as much more heat will not cause it to expand two or three inches more. Also, if a rod of gold, and another similar rod of glass, be heated to the same degree, their increments of bulk, arising thereby, will not be equal, the gold expanding more than the glass.

Of the three principal states of natural bodies, *viz.* solids, liquids, and elastic fluids, the solids are expanded least; the liquids are expanded more than the solids, but the elastic fluids are expanded a vast deal more than the liquids. The knowledge of the precise quantities of these expansions of bodies is of great use in philosophy, in mechanics, and in other scientific subjects; hence no pains have been spared by philosophers to investigate and ascertain them; various instruments have been contrived for that purpose; innumerable experiments have been instituted; and a great many useful results have been obtained. Of these results we shall now endeavour to give a regular and distinct account.

The instruments which have been contrived for the purpose of measuring the expansions of solids arising from an elevation of temperature, are called *pyrometers*. The objects which must be had in view in the construction of pyrometers, are to form a steady frame, wherein solids of a certain length may be applied either successively, or several of them at the same time, some contrivance by which those metallic bodies may be heated to any required degree, and a mechanism capable of measuring the increase of bulk which is caused by the heat; and this may be accomplished by means of multiplying wheels, by levers, by screws, by a microscopical micrometer, or otherwise. See PYROMETER.

Some of the first determinations of the expansion of bodies, that may be considered as being sufficiently accurate, were made by Mr. Ellicot with a pyrometer of his contrivance. Mr. Ellicot determined the proportional expansions of seven metallic bodies by the same elevation of temperature. They are as follows:

Gold.	Silver.	Brass.	Copper.	Iron.	Steel.	and Lead.
73.	103.	95.	89.	60.	56.	149.

Mr. Smeaton contrived a much better pyrometer, and with it he determined the expansions of several solids. Mr. De Luc also contrived a pyrometer of a peculiar construction; but Mr. Ramsden's pyrometer is superior to any other contrivance of the kind.

The following table shews, in parts of an inch, how much one foot length of different substances is expanded by 180° of heat, Fahrenheit's scale, between the freezing and the boiling

## EXPANSION.

boiling points of water. To the first seven substances, (which were examined in Mr. Ramsden's most accurate pyrometer,) there are added the expansions for a single degree of heat. The others were determined by Mr. Smeaton with his pyrometer.

Iron, instead of being condensed into a smaller bulk, expands in its transition from a fluid into a solid state; so that a quantity of iron occupies more room in the solid form than it does in a fused state.

Dr. Wollaston, in order to form some estimate of the comparative rate of expansion of platina and palladium, says, "I rivetted together two thin plates of platina and palladium, and observing that the compound plate, when heated, became concave on the side of the platina; I ascertained that the expansion of palladium is in some degrees the greater of the two. By a similar mode of comparison I found that palladium expands considerably less than steel by heat." Phil. Trans. for 1805.

It must be remarked with respect to the expansion of glass, that sometimes glass tubes are extended more than solid glass rods: their dilatation, however, is not constant; for tubes of different diameters, or of different sorts of glass, are expanded differently by the like degrees of heat.

Wood is not expanded much longitudinally; that is, in the direction of its fibres, by heat, and this is particularly the case with deal and other straight-grained wood. Pro-

bably, upon the whole, the longitudinal expansion of wood is less than that of glass. It has been observed, (especially by Dr. Rittenhouse, Trans. of the American Phil. Society) that very dry and seasoned wood, if not exposed to a very high or to a very low temperature, will expand in length pretty regularly: otherwise its expansion by heat, and its contraction by cold, are very irregular: for they seem to depend partly upon the heat, and partly upon the moisture, which the wood acquires in certain circumstances, and is deprived of in others.

It is hardly necessary to mention, that the solids of the preceding table contract their dimensions by cooling as much as they are expanded by heating; thus, for instance, if a yard length of any particular metallic body, by being heated 100° above the actual temperature of the atmosphere, be lengthened one fiftieth part of an inch; afterwards, when cooled down to the temperature of the atmosphere, it will be found to have lost exactly that fiftieth part of an inch which it had acquired by heating.

From the experiments hitherto made on the expansions of solids by heat, no correspondence has been observed between the expansions and the quantities of caloric they are capable of absorbing. The fusibility of metals seems to coincide with the dilatations; platina, the least fusible of the metals, dilates the least; lead dilates most; and the most fusible glass is also the most dilatable. We may therefore conclude with Mr. Berthollet, that bodies are so much the more expandible, the less caloric they require to change their constitution from solid to liquid, and from liquid to gases or vapours.

There is a substance which expands when heated; but does not contract when cooled; and of this singular property Mr. Wedgwood availed himself for the construction of his ingenious thermometer for measuring the highest degrees of heat; viz. those degrees which exceed the scale of the mercurial thermometer. (See THERMOMETER.) The substance alluded to is the argillaceous earth or clay, and it appears that the above-mentioned property belongs, more or less, to argillaceous bodies of every kind. This property may at first sight appear to be an unaccountable exception from the general law: the difficulty, however, will vanish, if it be considered that bodies of the argillaceous genus contain a considerable quantity of water, and that the contraction of these bodies, when exposed to the action of a strong fire, is in great measure due to the escape of the water, and hence they do not contract by subsequent cooling.

The method of measuring the expansions of fluids is to inclose them in a certain vessel, and to measure that part of the cavity of the vessel, which is occupied by the fluid under trial, in different temperatures. It is evident that the substance of the vessel is likewise expanded by the heat, and of course the cavity of the vessel is enlarged. Therefore, when we find that the bulk of the fluid is increased, that increment is only the difference between the enlarged capacity of the vessel and the increased bulk of the fluid. This shews the necessity of forming those vessels of such substances as are least expandible by heat. Indeed glass is the substance which is universally used for such purposes, both on account of its little expandibility, and of its transparency; besides its having other useful properties. A glass vessel, filled to a certain degree with a liquid, for the purpose of shewing the expansions of that liquid in different temperatures, or for the purpose of shewing the temperature of the corresponding expansion of that liquid, is called a thermometer; viz. a measure of the temperature. See THERMOMETER.

The properest shape for a thermometer is that of a long tube

## EXPANSION.

tube with a narrow bore, having a globular cavity at one end; which, familiarly speaking, may be called a globular glass bottle with a long and narrow neck. The globular cavity, and part of the tube of one of these vessels, is filled with the liquor whose expansion is to be examined, and the vessel is then heated, in consequence of which the liquor, which is contained in it, is expanded, and not being able to extend itself any other way, all the increment of bulk must be manifested in the tube; *viz.* the surface of the fluid will rise in the tube; or, if cooled, it will descend in it. If the same vessel of the above-mentioned shape be successively filled with different fluids, and with each fluid it be exposed to certain degrees of temperature, (which must be determined by an accurate thermometer,) the proportional expansions of the different fluids may thereby be ascertained. The same object may be obtained by filling several such vessels with the different fluids, that are to be examined, and heating or cooling them all at the same time; but in this case the corresponding capacities of the different vessels must be previously ascertained; which may be done by filling all the vessels with the same kind of fluid, and exposing them all to different degrees of temperature; so that the corresponding elevations of the fluid in the different vessels may be marked on the tubes. These vessels are afterwards emptied and filled again with the fluids, &c. Thus the proportional expansions of liquids may be determined; but when the actual or absolute increase of bulk is required, then the capacity of the vessel must be accurately gauged. This measurement of the capacity may be accomplished in the following manner. In the first place weigh the empty glass tube; secondly, fill part of the tube with a convenient fluid, (mercury, for instance, which is the fittest for such purposes); thirdly, measure the length of the tube which is occupied by the mercury, and weigh the instrument a second time; then, by subtracting this second weight from the former, you will have the weight of mercury which fills up a certain length of the cavity of the tube; fourthly, fill the bulb of the vessel entirely with mercury, and weigh the vessel a third time. This weight being subtracted from the first, *viz.* from that of the empty vessel, will leave the weight of the mercury in the bulb. Now, having the weight of the mercury in the bulb, as well as of that which fills a certain length of the tube, the ratio of the former to the latter may be easily determined by simple division. Also the absolute quantity in bulk of the former is obtained from the well known specific gravity of mercury, and from the weight of a cubic inch of distilled water, which (when the barometer is at 29.74 inches, and Fahrenheit's thermometer at 66°) is equal to 252.42 grains Troy; one pound Troy being equal to 5760 of those grains. An English cubic inch of mercury of the specific gravity 13.6 weighs 3443.2 English grains. Instead of mercury, some other fluid may be employed for this purpose; but not so conveniently as mercury. The expansions of a fluid, which are caused by different degrees of heat, may likewise be determined by ascertaining the specific gravity of that fluid in different temperatures; for the specific gravity decreases in proportion as the fluid is expanded, and *vice versa*; but this method is not capable of as much accuracy as the former.

Liquids differ from each other in regard to their expansibility; some expanding more than others. Also the expansions of the same liquid by equal degrees of heat are not quite regular; and it has been observed that this irregularity is greater when they approach the state of vapour. Upon the whole, mercury has been found to be expanded by

heat more regularly than any other fluid; yet its increments of bulk are not perfectly regular. Mr. De Luc, with great care and patience, has endeavoured to ascertain the real expansibility of mercury, or rather the real quantities of heat that are required for expanding mercury arithmetically, *viz.* by equal augmentations. These are expressed in the following table, the first column of which contains the degrees of Reaumur's scale, from five to five, which are equal parts; the second shews the real quantities of heat which are required to raise the mercury to the corresponding degrees, where *z* is a fixt but unknown quantity; and the third column shews the differences of those quantities. De Luc's Recher. sur les Modif. de la Atmosph. 1772, p. 309.

	Mercurial Thermom.	Real quantities of heat.	Real differences of heat corresponding to the variations of the Mercury in the thermometer from 5 to 5 degrees.
Point of boil. water	80°	<i>z</i> + 80.00	
	75	<i>z</i> + 75.28	-4.72
	70	<i>z</i> + 70.56	-4.72
	65	<i>z</i> + 65.77	-4.79
	60	<i>z</i> + 60.96	-4.81
	55	<i>z</i> + 56.15	-4.81
	50	<i>z</i> + 51.26	-4.89
	45	<i>z</i> + 46.37	-4.89

	35	<i>z</i> + 36.40	-5.00
	30	<i>z</i> + 31.32	-5.08
	25	<i>z</i> + 26.22	-5.10
	20	<i>z</i> + 21.12	-5.10
	15	<i>z</i> + 15.94	-5.18
	10	<i>z</i> + 10.74	-5.20
	5	<i>z</i> + 5.43	-5.31
Point of melt. ice	0	<i>z</i>	-5.43

From the third column it appears, that the differences of heat requisite to make equal and progressive additions to the bulk of the mercury, though not exactly equal, yet are not very far from the ratio of equality. If the bulk of a quantity of mercury, at the temperature of 32° Fahrenheit's scale, be conceived to be divided into 100,000 equal parts, and then be heated as high as the temperature of boiling water; (*viz.* 212°) its bulk will thereby be increased by 1836 of those parts.

The expansion of water is attended with a singular deviation from the general law; *viz.* this fluid is expanded by heat from about the 40th degree of Fahrenheit's thermometer upwards; but below 40° its bulk is expanded by a farther decrease of heat, or increase of cold; and in fact ice is lighter than water, so as to float upon it; the specific gravity of ice being to that of water nearly as 7 to 8. The bulk of ice is to that of the water, when the ice is melted, as 9 to 8 very nearly. The bulk of water, from its most contracted state at the temperature of 40°, increases continually; but that increase is not very regular; for instance, the increase of bulk from 180° to 212°, is considerably greater than from 40° to 72°. If the bulk of water at 40° be called 1, its bulk at 212° will be 1.04785. Beyond that degree of heat water becomes vapour; *viz.* an elastic fluid, and the formation of this elastic fluid on the sides of the vessel within the water, forms the bubbles, the escape

## EXPANSION.

of which constitutes the boiling. The bulk of steam at the boiling point is somewhat less than 1800 times the bulk of the water from which it originated.

The expansion of freezing water is not owing to the extrication of air; for water deprived of air expands like other water in freezing. Mr. Mairan attributes it to a strong tendency the particles of water have to arrange themselves into ranks and lines, which cross one another at angles of 65° and 120°. This tendency seems to begin at the temperature of 40°. The expansion of freezing water has a prodigious force. It is owing to this that in hard frosts timber is burst, plaster is removed from walls, and even iron mortar shells filled with water, and accurately stopped, have been burst by the freezing of the water.

This singular property of water, viz. its expanding from the temperature of 40° downwards, so as to become lighter and lighter in proportion as it becomes colder and colder, is a most striking instance of the wisdom of the Creator, and is a property of immense consequence to the very existence of animals and vegetables. A quantity of water is indispensably necessary to animals and to vegetables at all times of the year. In winter, when the cold air freezes the surface of the water, that effect seldom penetrates lower than two or three feet. Below that depth the water continues fluid, and the crust of ice itself contributes to preserve its fluidity. The heat of the earth, which has been acquired during the summer, undoubtedly prevents the formation of ice below a certain depth. But if water in cooling had continued to increase in specific gravity, and had ice been actually heavier than water, the heat of the earth would not have been sufficient to prevent the total freezing of all the waters of lakes, seas, rivers, &c. "For," says count Rumford, "as the particles of water on being cooled at the surface would, in consequence of the increase of their specific gravity, on parting with a portion of their heat, immediately descend to the bottom, the greatest part of the heat accumulated during the summer in the earth, on which the water reposes, would be carried off and lost before the water began to freeze; and when ice was once formed, its thickness would increase with great rapidity, and would continue increasing during the whole winter; and it seems very probable that in climates which are now temperate, the water in the large lakes would be frozen to such a depth in the course of a severe winter, that the heat of the ensuing summer would not be sufficient to thaw them; and should this once happen, the following winter would hardly fail to change the whole mass of its waters to one solid body of ice, which never more could recover its liquid form, but must remain immovable till the end of time." (7th Essay.)

The following table shews the expansions of the principal liquids that have been submitted to such experiments, according to Mr. De Luc's observations. With respect to this table it must be understood that different thermometers (each being filled with a particular fluid, such as is mentioned at the top of each column, and each being divided into 80 equal parts between the freezing and the boiling points of water) are placed with their bulbs in the same vessel full of water, and that the water is gradually heated. When the mercurial thermometer stands at 5°, 10°, 15°, &c. the surfaces of the fluids in the other thermometers will be found at the degrees which stand on the same levels; for instance, when the mercurial thermometer stands at 40°, the water thermometer will be found to stand at 20°.5, the spirit thermometer will be found to stand at 35°, the oil thermometer at 39°.2, &c.

The expansions of elastic fluids, such as common air, the gases, and vapours, are more difficultly ascertained; for the expansions of those fluids are occasioned by a diminution of pressure, as well as by an increase of temperature; and it is difficult to subject any of those fluids to the action of one of these causes only at a time, in order that the effect of each may be duly estimated.

When common air is acted upon by pressure only, independent of any alteration of temperature, its bulk is found to increase and to decrease in the inverse proportion of the pressure; thus, the air close to the surface of the earth is compressed into the bulk which we experience, by the superincumbent atmosphere. If that pressure be increased, the bulk of the lower air will be contracted, which is manifested by an augmentation of its weight; if that pressure be diminished, the bulk of the lower air will be increased, as is manifested by a diminution of its weight. And this expansion and contraction of the air is exactly but inversely proportional to the pressure; so that a double pressure will compress it into half the space, a treble pressure into one third of the original space, &c. The same thing, *mutatis mutandis*, may be said of the removal of pressure, and of the expansion thereby arising. This elasticity of the air has not been found to be impaired by a long continuance of the pressure; for air has been left during several years very much compressed in proper vessels, wherein there was nothing that could have a chemical action upon it; and afterwards on removing the unusual pressure, and replacing it in the same temperature, the air has been found to recover its original bulk. It is not known how far a quantity of air may be expanded by removing the pressure, nor how much it may be compressed by increasing the pressure; for no experiments have as yet been able to ascertain either limit.

The instrument, in which the expansion of air is tried, has been called *manometer*, (which see.) It is a sort of large air thermometer, consisting of a tube five or six feet long, having a bulb at one end, and being open at the other end. The bore of the tube is about a 20th of an inch in diameter. A small quantity of quicksilver is placed in some part

## EXPANSION.

part of the cavity of the tube, and the expansion of the air in the bulb, when heated, forces the quicksilver to move towards the open end of the tube. The degree of heat to which the manometer is exposed is measured by means of a thermometer; the quantity of expansion of the air is measured by gauging the manometer, and making marks on the tube, which may indicate parts of the cavity of the tube that are proportional to the capacity of the manometer; as for instance 100ths, 1000ths, &c. By placing the manometer horizontal or vertical, either with the bulb downwards or upwards, the air in it may either be left of the natural density, or it may be condensed, or, lastly, it may be rarefied; for when the manometer stands horizontal, the quicksilver in the tube does not press upon the air in the bulb, nor on that of the atmosphere; when the bulb is downwards, the quicksilver presses upon the air of the manometer, and when the bulb is upwards, the quicksilver presses against, and counteracts, in some measure, the gravity of the atmosphere. Hence this pressure, and this expansion of the air within the manometer, may be increased to any required degree by increasing the quantity of quicksilver within the tube: and thus the expansibility of common, or of condensed, or of rarefied air, may be tried. The expansion of air, by the same degrees of heat, differs according to its density, and to the quantity of moisture it contains; nor are the increments of its bulk proportional to the degrees of temperature.

It appears from Col. Roy's very numerous experiments (Phil. Transf. vol. 67th) that 1000 parts of air, of the density of the common atmosphere, at 0° of heat, become 1484.21 at 212°; viz. are expanded 484.21, by 212° of heat.

1000 parts of air loaded with  $2\frac{1}{2}$  atmospheres, are expanded 434 of those parts, by 212° of heat.

1000 parts of air pressed only with  $\frac{1}{8}$ ths of an atmosphere, are expanded nearly 484 of those parts by 212° of heat.

1000 parts of air pressed with  $\frac{1}{4}$ th of an atmosphere, are expanded about 141 parts by 180° of heat; viz. from the freezing to the boiling point of water.

"From these last experiments," Col. Roy says, "it would seem that the particles of air may be so far removed from each other, by the diminution of pressure, as to lose a very great part of their elastic force."

The above-mentioned expansions of air are by no means regular: viz. they are not proportional to the number of the degrees of heat. The maximum of expansion takes place between 52° and 72°: and the minimum is constantly at the boiling point of water. Moist air expands a great deal more than dry air, especially when it approaches the boiling point of water; so that between 192°, and 212°, moist air expands about eight, or nine, times as much as dry air in similar circumstances.

The expansions of gases may be tried and determined in the same manner as the expansion of common air. From a long series of experiments, Messrs. Guyton and Prieur deduced a dilatation peculiar to each gas; but Mr. Guy-Lussac has shewn, that all gases, without exception, possess the same expansibility at the same degree of temperature, and that the presence of water in gases occasioned the errors into which his predecessors had fallen. He is led to conclude from his experiments made on gases reduced to the utmost degree of dryness, that 100 parts of each of the permanent gases acquire an increase of  $\frac{1}{273}$  by every degree of the thermometer from 0° to 80° Reaumur's scale. Vapours, he also thinks, follow the same laws of dilatation as gases, provided the temperature be sufficiently elevated to keep them in the elastic state. Therefore, Mr. Chaptal says, it may be laid

down as a principle, that gases and vapours are equally dilat-able, and equally compressible; but it will be necessary to be more particular with respect to the expansibility of the vapour of water, upon the elasticity of which numerous natural phenomena, and the action of several important machines, depend.

Mr. Schmidt also made a series of experiments upon the expansibility of air, made as dry as possible by exposure to hot potash. He found the expansion of a quantity of air which measured one inch at the freezing point, viz. at the temperature of 0° Reaumur's thermometer, to expand as below.

Degrees of Reaumur.	Expansion of one inch.

This table also shews, by its differing from the results of D'Amontons, De Luc, Lambert, Schuckburgh, Berthollet, and others, that those gentlemen operated upon air more or less charged with moisture. They also took the barometers at different altitudes. In Mr. Schmidt's experiments the barometer was taken at 29,841 English inches. These variations of the rates of expansibility of moist air, saturated at different temperatures, Schmidt attributes to the variations of the degrees of affinity between air and vapour.

Water heated to the 212th degree of Fahrenheit's thermometer (or thereabout, for the different gravity of the atmosphere occasions a considerable difference) overcomes the ordinary pressure of the atmosphere and becomes steam, an elastic substance, the bulk of which at that point is somewhat less than 1800 times the bulk of the water from which it originated. Beyond that point vapour is expansible in a most astonishing degree; for 30° more of heat (viz. the temperature of 242°) will double the elastic force of steam; 30° more added to that (viz. the temperature of 272°) will render the elastic force of steam nearly equal to four atmospheres; and so forth. This immense expansibility of steam, when the heat which produces it is quickly supplied, is capable of producing prodigious effects. When water is caused to boil in a vessel upon a common fire, the heat which is communicated cannot convert all the water at once into steam; but if the quantity of water be small in proportion to the heat which can be communicated in a given time, then the conversion of water into steam is quickened to any degree, and it may be rendered instantaneous; in which case it produces a sudden and violent expansion, or an explosion. A drop of rain in boiling linseed oil, falls to the bottom, is instantly converted into vapour, and occasions dangerous consequences. "It has sometimes," Dr. Black says in his Chemical Lectures, "happened that a person, by carelessly spitting into a copper foundery, has occasioned an explosion that destroyed the whole building." Count Rumford attributes the vast force of gun-powder to the sudden conversion into vapour of that quantity of water which naturally enters into the composition of that powder; it being a component of the nitre. Phil. Transf. for 1797.

## EXPANSION.

Water at the temperature of  $212^{\circ}$  is converted entirely into steam, or rather, under the ordinary pressure of the atmosphere, water cannot be heated higher than  $212^{\circ}$ ; but water is gradually converted into steam or vapour at a much lower temperature. Mr. Pictet instituted a series of experiments on the elasticity of pure vapour in low temperatures. He found that a grain of warm water in vacuo evaporates in forty minutes in the temperature of  $38^{\circ}$  Fahr. under a receiver containing 1452 English cubic inches, but that it did not diffuse itself equally in less than six hours and then raised the hygrometer from  $17^{\circ}$  to  $65^{\circ}$ , that is,  $43^{\circ}$ ; and during this whole time the cold under the receiver was constantly decreasing, though slowly: which decrease undoubtedly contributed to the diffusion of the vapour. *Essais de Physique*, p. 157.

The best, or most extensive experiments upon the expansive force of the steam of water, and of the steam of alcohol, were made by the Chev. de Bettancourt; and are related by Prony in the second volume of his "Architecure Hydraulique;" from which the following compendious sketch is derived.

The fluid with which the experiments were made was confined in a very strong copper boiler, being eight inches at its greatest diameter, and fourteen inches in height. The upper part of it was closed by a cover made of copper, through which passed three tubes. The first served to introduce the fluid into the boiler, and could be closed by means of a screw. The second was occupied by a thermometer, having its ball about two inches above the bottom of the boiler, and the scale, which was on the outside, contained from  $0^{\circ}$  to  $110^{\circ}$  of Reaumur. To the third was adapted a bent barometer tube, having two lines of internal diameter; the ascending branch of which was 110 inches in length. By means of a lateral cock a communication was established between the boiler and an air-pump, which served to make a vacuum before the fire was kindled in the furnace below the apparatus. This circumstance of evaporation in a vacuum forms an essential difference between the experiments of Bettancourt and those made before by Ziegler, and renders them applicable to the theory of the steam-engine, where the vapour acts in a space freed from air.

A vacuum having been made in the boiler, the mercury brought as nearly as possible to a level in the two branches of the barometric tube, and the thermometer reduced to zero by means of ice, the ice was removed, and a fire was kindled, which was excited gently and with much equality, that the thermometer passed over about a degree per minute. One person then stood by to observe the barometer, and another to observe the thermometer, and each kept a register from degree to degree of the pressure and corresponding temperatures; the pressure being expressed by the height, in French inches, of the columns of mercury, which rose above the level in the long branch of the barometer.

These observations of the expansive force of the steam of water furnish 110 results, proceeding from degree to degree of the thermometer, and beginning at zero. These results are contained in the following table, where the degrees of pressure are expressed in French inches of perpendicular height of mercury, and the temperature is denoted according to Reaumur's scale. The experiments on the expansive force of the steam of alcohol were made by the like process, and with the same apparatus.

TABLE of the Expansive Force of the steam of Water and of Alcohol.

The expansive force of the steam of water has also been determined by Mr. Schmidt, with all the accuracy that the experiments seem to admit of: but the results which he has not stated for every degree of the thermometer, do not agree exactly with those of Bettancourt. We deem it therefore necessary to subjoin those results in the following short table, wherein the temperature is expressed in degrees of Reaumur's thermometer, as in the preceding table, and the expansive force in French inches of perpendicular altitude of mercury.

TABLE of the Expansive Force of the pure vapour of Water, according to Mr. Schmidt.

Temperature.	Expansive Force.	Temperature.	Expansive Force.
0	0.0	22	1.01
5	0.11	25	1.30
6	0.15	27	1.42
10	0.28	30	1.93
12	0.38	33	2.23
13	0.44	35	2.68
15	0.55	37	3.20
16	0.61	39	3.40
18	0.76	40	3.64
20	0.90	80	28.00

Mr. Dalton has likewise endeavoured to determine the expansive force of the vapour of water; but the results of his experiments nearly coincide with those of the preceding tables, which supercedes the necessity of stating them in the present article. See EVAPORATION.

From a careful examination of all the experiments made on this subject, Dr. Young has deduced a formula by which the expansive force of steam may be determined for any degree of the thermometer, pretty near the real results of the experiments. The formula is as follows:

Let  $f$  denote the temperature according to Fahrenheit's thermometer, and  $e$  the number of inches in perpendicular height of mercury, which the steam is capable of supporting; then the formula is  $e = .1781 (1 + .006 f)^2$ .

The reader might perhaps expect to find in the present article the particulars relative to the expansions of heat, and of electricity; but the uncertain natures of the fluids, to which the effects of heat and of electricity are attributed, besides other considerations, oblige us to refer him to other parts of this Cyclopædia. See HEAT, CALORIC, and the articles belonging to electricity.

Dr. Gregory, in his Astron. p. 407, proves, that a globe of our air, of an inch diameter, if it were removed to the distance of a semidiameter of the earth, would expand itself so as to fill all the planetary region as far as nay, far beyond the sphere of Saturn. See AIR.

EXPANSUM FOLIACEUM. See FOLIACEUM.

EX PARTE, i. e. partly, or of one part, in Law. A commission ex parte, is that taken out and executed by one part only; where both parties join it is called a joint commission. See COMMISSION.

EX PARTE TALIS, a writ that lies for a bailiff or receiver, who, having auditors assigned to take his account, cannot obtain of them reasonable allowance, but is cast into prison. The course in this case is to sue this writ out of chancery, directed to the sheriff, to take four mainperners to bring his body before the barons of the exchequer at a certain day, and to warn the lord to appear at the same time. F. N. B. 129.

EXPECTANT FEE, where lands are given to a man and his wife, and the heirs of their bodies; in which sense it differs from fee-simple, where lands are given to a man and his wife in frank marriage, to hold to them and their heirs.

EXPECTANCY, ESTATES IN, are of two sorts; one created by act of the parties, called a remainder; the other by act of law, called a reversion. See these articles; and also ESTATE and EXECUTORY Devise.

EXPECTATION, in the Doctrine of Chances, is applied to any contingent event, and is capable of being re-

duced to the rules of computation. Thus, a sum of money in expectation, when a particular event happens, has a determinate value before that event happens; so that if a person is to receive any sum, e. gr. 10*l.* when an event takes place which has an equal probability of happening and failing, the value of the expectation is half that sum or 5*l.* and in all cases, the expectation of obtaining any sum is estimated by multiplying the value of the sum expected by the fraction, which represents the probability of obtaining it. The expectation of a person who has three chances in five of obtaining 100*l.* is equal to  $\frac{3}{5} \times 100$  or 60*l.* and the probability of obtaining 100*l.* in this case is equal to  $\frac{3}{5} = \frac{60}{100}$ .

If the obtaining of any sum requires the happening of several events that are independent on each other, the value of the expectation of that sum is found by multiplying together the several probabilities of happening, and by multiplying the product by the value of the sum expected. E. gr. Suppose, that in order to obtain 90*l.* two events must happen, one of which has three chances to happen and two to fail, and the other has four chances to happen, and five to fail; the value of the expectation is  $= \frac{3}{5} \times \frac{4}{9} \times 90 = \frac{12}{45} \times 90 = 24*l.*$  for if the first event had actually happened, the value of the expectation depending solely on the second event, would be  $\frac{4}{9} \times 90 = 40*l.*$  and therefore the happening of the first event is the condition of obtaining an expectation worth 40*l.* but the probability of the first happening is  $\frac{3}{5}$ , and the expectation sought for is evidently worth  $\frac{3}{5} \times 40 = \frac{3}{5} \times \frac{4}{9} \times 90 = 24*l.*$  The rule will be the same if an expectation depends on the happening of one event and the failing of another; and also on the failing of two events; and on the happening or failing of any number of events that may be assigned. It is here supposed that the events are independent, or that the happening of one, neither forwards nor obstructs the happening of the other. But if two events are dependent, i. e. if they are so connected together as that the probability of either's happening is altered by the happening of the other, the probability of their happening is the product of the probability of the happening of one of them by the probability which the other will have of happening, when the first is considered as having happened; and the same rule will extend to the happening of any assigned number of events: thus, in a heap of thirteen cards of the same colour, the probability of taking out the ace is  $\frac{1}{13}$ ; and the probability of taking the ace out of another heap of the same number is  $\frac{1}{13}$ ; and the probability of both these independent events happening will be  $\frac{1}{13} \times \frac{1}{13} = \frac{1}{169}$ : but the probability of taking the ace first out of a single heap of thirteen cards is  $\frac{1}{13}$ ; and that of taking the deuce afterwards is  $\frac{1}{12}$ ; and therefore the probability of both happening is  $\frac{1}{13} \times \frac{1}{12} = \frac{1}{156}$ . If a person has several expectations on several sums, the value of his expectation on the whole is the sum of his expectations on the particulars: thus, let one event be such, that the probability of obtaining any sum, e. gr. 90*l.* in case it happens, may be  $\frac{3}{5}$ ; in which case the value of the expectation is  $\frac{3}{5} \times 90 = 54*l.*$  Let the probability of another event, on which depends a second sum of 90*l.* be  $\frac{4}{9}$ , and the value of the expectation in this case be  $\frac{4}{9} \times 90 = 40*l.*$  and the value of the expectation on the whole  $54 + 40 = 94*l.*$  But if a person is to receive 90*l.* once for all for the happening of one or other of the two forementioned events, then the expectation of the first event being worth 54*l.* as before, yet the expectation of the second will be different; because this depends on the happening of the first, and takes place only in case the first happens to fail, the probability of which is  $\frac{2}{5}$ ; and

# EXPECTATION.

on the supposition of its having failed, the expectation of the second will be 40%; therefore  $\frac{2}{3}$  is the measure of the probability of obtaining an expectation worth 40%; and consequently the expectation will be worth  $\frac{2}{3} \times 40 = 16\frac{2}{3}$  and the value of the expectation on the whole will be  $54 + 16\frac{2}{3} = 70\frac{2}{3}$ . See the farther illustration and application of these principles and rules in De Moivre's *Doctrinae of Chances*, edit. 3. 1776. See CHANCES and GAMING.

EXPECTATION of Life, in the *Doctrinae of Life Annuities*, denotes, according to the most obvious sense of the term, that particular number of years which a life of a given age has an equal chance of enjoying, or the time which a person of a given age may justly expect to continue in being. But Mr. Simpson has shewn, that this period does not coincide with what the writers on annuities call the expectation of life, except on the supposition of an uniform decrease in the probabilities of life; and Dr. Price adds, that even on this supposition, it does not coincide with what is called the expectation of life, in any case of joint lives: for two lives of 40 have an even chance, according to Mr. De Moivre's hypothesis (see *COMPLEMENT of life*) of continuing together only  $13\frac{1}{2}$  years. According to that hypothesis, the probability that a life aged 40 will continue  $13\frac{1}{2}$  years will be expressed by  $\frac{32.5}{46}$ ; and this fraction multiplied by itself is the probability that two lives of this age shall both continue  $13\frac{1}{2}$  years; i.e.  $\frac{32.5}{46} \times \frac{32.5}{46} = \frac{1056.25}{2116}$ , equal nearly  $\frac{1}{2}$ , which represents an even chance; but the expectation of two joint lives being (according to the same hypothesis) always a third of the common complement, will be in this case  $15\frac{1}{3}$  years. Therefore, the expectation of life may signify the mean continuance of any given single, joint, or surviving lives, according to any given table of observations, or the number of years which, taking them one with another, they actually enjoy; so that if 46 persons are alive, all 40 years of age, and one be supposed to die every year, according to Mr. De Moivre's hypothesis, till they are all dead in 46 years, half 46 or 23 will be their expectation of life; i.e. the number of years enjoyed by them all will be the same as if every one of them had lived 23 years, and then died; and supposing no interest of money, the value of an annuity payable for life to every single person in such a set, would just be equal to 23 years purchase.

The expectation of life coincides with the sums of the present probabilities, that any given single or joint lives shall attain to the end of the first, second, third, &c. moments, from this time to the end of their possible existence; or (in the case of survivorships) with the sum of the probabilities, that there shall be a survivor at the end of the first, second, third, &c. moments, from the present time to the end of the possible existence of survivorship. From these principles Dr. Price has shewn how to deduce the demonstrations of Mr. De Moivre's rules for finding the expectations of lives, which he has omitted; we shall here subjoin them for the information and amusement of our mathematical readers. Let  $\dot{x}$  stand for a moment of time, and  $n$  be the complement of any assigned life; then  $\frac{n-\dot{x}}{n}$ ,  $\frac{n-2\dot{x}}{n}$ ,  $\frac{n-3\dot{x}}{n}$ , &c. will be the present probabilities of its continuing to the end of the first, second, third, &c. moments; and  $\frac{n-x}{n}$  the probability of its continuing to the end of  $x$  time: therefore,  $\frac{n-x}{n} \times \dot{x}$  will be the fluxion of the sum of the probabilities, or of an area representing this sum, whose ordinates are

$\frac{n-x}{n}$ , and axis  $x$ . The fluent of this expression, or  $x - \frac{x^2}{2n}$ , is the sum itself for the time  $x$ ; and this, when  $x = n$ , becomes  $\frac{1}{2}n$ , the expectation of the assigned life, or the sum of all the probabilities just mentioned for its whole possible duration. In like manner  $\frac{n-x}{n} \times \frac{n-x}{n}$  or  $\frac{(n-x)^2}{n^2}$  is the probability that two equal joint lives will continue  $x$  time, and  $\frac{(n-x)^2}{n^2} \times \dot{x}$  will be the fluxion of the sum of the probabilities; the fluent of which, or  $x - \frac{x^2}{n} + \frac{x^3}{3n^2}$ , becomes, when  $x = \frac{n}{3}$ , or the expectation of two equal joint lives. Again, since  $\frac{n-x}{n} \times \frac{2x}{n}$  is the probability that there will be a survivor of two equal joint lives at the end of  $x$  time,  $\frac{n-x}{n} \times \frac{2x}{n} \times \dot{x}$  will be the fluxion of the sum of the probabilities; and the fluent, or  $\frac{x^2}{n} - \frac{2x^3}{3n^2}$ , is, when  $x = n, \frac{2}{3}n$ , or the expectation of survivorship between two equal lives, which appears to be equal to the expectation of their joint continuance. The expectation of two unequal joint lives found in the same way is  $\frac{m}{2} - \frac{m^2}{6n}$ ,  $m$  being the complement of the oldest life, and  $n$  the complement of the youngest. The whole expectation of survivorship is  $\frac{n}{2} - \frac{m}{2} + \frac{m^2}{3n}$ ; and the expectation of survivorship of the oldest will be to that of the youngest as  $\frac{m^2}{6n}$  to  $\frac{n}{2} - \frac{m}{2} + \frac{m^2}{6n}$ .

From the definition already given of the expectation of life, it follows, that if in a society limited to a fixed number of members, a 28th part of its members dies annually, 28 would appear to be their common expectation of life at the time they entered; and if it were found in any town or district, where the number of births and burials are equal, that a 20th or 30th part of the inhabitants die annually, it would appear that 20 or 30 was the expectation of a child just born in that town or district.

Having a table of observations, shewing the number that die annually at all ages out of a given number alive at those ages, it is easy to find the expectation for all single lives by the following rule: divide the sum of all the living in the table at the age whose expectation is required, and at all greater ages, by the number in the table of the living at that age, and subtract half unity from the quotient, the remainder will be the expectation required.

The reason of this subtraction may be understood by conceiving the recruit necessary to supply the waste of every year to be made always at the end of the year, so that the dividend ought to be the medium between the number living at the beginning and the end of the year; that is, it should be taken less than the sum of the living in the table at and above the given age by half the number that die in the year; the effect of which diminution will be the same with the subtraction here directed. This rule may be illustrated by taking the sum of all the living at 20 and upwards in Tab. I. and dividing it by 360, the number living at that age, and the quotient less half unity, will be nearly 28.9 the expectation of 20 in Tab. II.

# EXPECTATION.

80	4 $\frac{1}{2}$	4 $\frac{1}{2}$	5	5	5 $\frac{1}{2}$	6

Dr. Price has applied his reasoning on this subject to the solution of a curious question in political arithmetic, or to determine the number of inhabitants in any place from a table of observations, or the bills of mortality for that place, on the supposition that the yearly births and burials are equal. For this purpose find by the table the expecta-

tion of an infant just born; and this, multiplied by the number of yearly births, will be the number of inhabitants

Were the bills of mortality constructed with the least regard to truth, and were a regular account kept of all the persons who annually migrate from the country, this rule of Dr. Price might be safely applied towards ascertaining the number of inhabitants in London, but in their present form the London tables are so very incorrect that it can hardly be safe to derive any conclusions from them.

It appears from Tab. I. that though an infant just born in London has not an equal chance (the probability being  $\frac{1000}{10000}$ ) of living three years, his expectation is twenty years, and by Tab. III. that though the expectation of such a child in Northampton is twenty-five, it has only an equal chance of living eight years. This difference proceeds from the greater probability of life in the more mature ages, than in the first moments of existence. Were the decrements of life, however, the same through every period of it, these quantities would always be equal; but as this is not the case, neither in the earlier nor the latter ages, the computations founded on such an hypothesis can in general be of very little use. De Moivre's Doctrine of Chances; applied to the Valuation of Annuities, p. 288, &c. Simpson's Select Exercises, p. 253, &c. and particularly Dr. Price's Observations on Reversionary Payments, eff. i. vol. ii. or Phil. Trans. vol. lix. p. 89. See COMPLEMENT of Life, LIFE ANNUITIES, MORTALITY, SURVIVORSHIP.

EXPECTATIVE, in the Canon Law, a hope founded on a promise of obtaining the next benefice that shall become vacant, or a right to the reversion of the next. See BENEFICE.

EXPECTATIVE Canons. See CANON.

EXPECTATIVE Graces, *Gratie Expectativa*, called also *preventions*, were bulls frequently given by the popes or kings for future benefices. The bishops were exceedingly mortified with them, because they encroached on their privileges; besides, that such expectatives are odious, as they induce people to wish for the death of others.

The use of expectatives is very ancient, though it was not near so frequent in the first ages as afterwards. Originally they were no more than simple requests made on the part of kings or popes, which the bishops consented to with the more willingness, as they only presented to them persons fit to serve the church; but the frequent exercise of this privilege made it at length be deemed a matter of obligation and necessity.

The council of Trent annulled all expectatives; but the canons relating thereto were never admitted in France, where the right of conferring expectative graces is looked on as one of the regalia.

EXPECTORANT MEDICINES, are those which facilitate the excretion of the mucous discharges from the cells and passages of the lungs; or *expellere*, from the breast.

This evacuation must be accomplished by more or less of coughing, which the irritation of the collecting mucus, &c. naturally occasions. It were, therefore, obviously useless and superfluous to give medicines with a view to excite coughing, (if indeed we were acquainted with any substance possessed of such quality,) or to use any external means, as the ancient Cnidians are said to have done, for that purpose. The principal object, in attempting to facilitate the discharge of the contents of the bronchial vessels and cells, must consist in changing the nature of those contents, so as to render them thinner, less tenacious, and more moveable than before. Whether we are possessed of any medicines, however, capable of producing such a direct effect, may admit

mit of a question. The generality of writers on the materia medica, and of physicians, speak of the utility of such medicines as they have termed *attenuantia* and *incidentia*, for this purpose: but we believe, with Dr. Cullen, that their hypothesis on this subject is altogether erroneous, and that no such medicines exist. The only probable explanation of the action of an expectorant medicine appears to be, that by increasing the secretion from the exhalent arteries in the lungs, the mucus may be diluted and rendered less viscid and the passages from the cells may be more fully moistened with a less tenacious fluid. We know that there is a constant and considerable exhalation of moisture from the cavity of the lungs; and there are many reasons for believing that this is an excrementitious secretion, connected with the other excrementitious secretions, particularly with the perspiration from the surface of the body. If, therefore, there are medicines disposed to pass by perspiration, it may be presumed that the same are disposed to pass by the exhalation from the lungs: and this exhalation may not only be increased, but the mucus, produced by the follicles, may also be poured out in a less viscid form, and consequently in a state to be more easily brought up by expectoration.

It would appear, that some such increase of the thinner secretion of lungs is produced, by sympathy with the stomach, when a condition approaching to nausea is induced, and that, therefore, medicines which possess an emetic quality, when used in small doses, operate in some degree as expectorants; such as the squill, ipecacuanha, nicotiana, antimony, &c. A full dose of an emetic seems to produce this effect more completely, and affords considerable relief to those asthmatic complaints, as they are called, in which the lungs are loaded with a quantity of viscid phlegm. Many expectorant medicines are mentioned by different writers, such as the tussilago, or colt's foot, enula campana, iris florentina, petasites, &c. which recent experience seems to have rejected, from their failure to answer the expectation which those writers had excited.

Many other medicines which give relief to coughs have been employed under the appellation of expectorants; but their operation is to be explained upon principles altogether different from that of facilitating expectoration. Among these are spermaceti, liquorice, oil of almonds, and other vegetable and animal oils, various mucilaginous vegetables, such as mallow, horehound, &c. all of which give a temporary alleviation to the irritation about the glottis, and thus appease the cough, but do not in the smallest degree aid the expectoration. See CATARRH.

In the chronic coughs of old people, expectoration appears to be facilitated by the use of the stimulant gums, and of volatile alkali. But perhaps these medicines operate indirectly, by supporting the strength of the patients, and thus enabling them to use greater muscular exertion in the act of coughing.

EXPECTORATION, the act of bringing up the mucous and other excretions from the lungs, by coughing, hawking, &c. The word has the same derivation as the preceding.

EXPEDITATION, in the *Forest-Laws*, signifies a cutting out the balls of a dog's fore-feet for the preservation of the king's game.

Every one that keeps any great dog, not expeditated, forfeits three shillings and four-pence to the king. In mastiffs, not the ball of the feet, but the three claws, are to be cut to the skin. Instit. part. iv. p. 308. "Nullos Dominicos canes abbatis & monachorum expeditari cogat." Chart.

Hen. III. "Et sin quieti de expeditamentis canum." Ex. Mag. Rot. Pip. de ann. 9 Ed. II.

The expeditation was to be performed once in every three years, and was done to every man's dog who lived near the forest, and even the dogs of the foresters themselves.

EXPEDITION, the march of an army to some distant place, with a view of hostilities.

Such were the expeditions of Cyrus against Xerxes, and of Bacchus and Alexander to the Indies.

Expeditions for the recovery of the Holy Land were called croisades.

The success of an expedition depends on rapid and unexpected movements. An expedition is planned and governed by the following principal maxims, viz. secrecy, if possible, of preparation, and a concealment of design, &c.; a just proportion of the means to the end; a knowledge of the state and situation of the country, which is intended to be the scene of action, and of the place or object that is to be attacked; the appointment of a commander, possessed of those abilities, and of that disposition, which are adapted to the warfare proposed; and the arrangement of the plan of the expedition before it is undertaken or carried into effect. The French use the word expedition to express any particular military quality, which an officer or soldier may possess. Thus, "cet officier est un homme d'expedition," that is, this officer is a man of enterprise, or courageous and daring.

EXPENCES, in *Book-keeping*. See *Book of Expences*.

EXPENDITORS, in *Law*, are the persons appointed by commissioners of sewers, to pay, disburse, or expend the money collected by the tax for the repairs of sewers, &c. when paid into their hands by the collectors on the reparations, amendments, and reformations ordered by the commissioners; for which they are to render accounts when required for that purpose.

These officers are mentioned in the statute 37 H. VIII. cap. 11. and other statutes. The steward who supervises the repair of the banks and water-courses in Romney Marsh is likewise called the expeditor.

EXPENSE MAGAZINE, is a small receptacle for such quantities of ammunition as may be required on emergency, or for the supply of powder, &c. in that ordinary course which enables the proper officers to estimate with correctness what quantity should be kept at hand for the purpose of annual exercise, or for the furnishing the neighbouring camps, posts, or batteries, with such stores as may be necessary for their use. Thus we see, in almost every fortress, various expense-magazines built in commodious and safe situations, for the express purposes of enabling the commissaries, and the ordnance officers, to prevent the defenders of the several works in their vicinity from being at a stand for want of ammunition. Some of these little stores are occasionally built even upon the terre-pleine of the batteries they are to supply; but we have heard this practice censured; for, though it may be true, that owing to their very solid construction they may successfully resist the enemies' shot, still, as they are liable to explode from other accidents, we cannot join an unqualified approval of such positions. We avail ourselves of a suggestion offered to us, in which we think the foregoing objection is greatly diminished, if not totally removed. The suggestion is, that in lieu of allowing any expense-magazines to be built on a terre-pleine, a ramp should be thrown up at the back of every sixth or seventh piece of ordnance on the defences, the interior of which should be a magazine of this description. The ramp would serve as a passage for the persons employed in conveying the powder to the gunners, and should have a door at that side

least exposed to enfilades, or to accidental shots. The entrance might, indeed, be either above or below the ramp; though we are disposed to recommend the latter; as the delay occasioned by ascending would not be of any consequence in ordinary defences, and would be fully counter-balanced by the safety with which all the expense-magazines might be worked. Possibly, the suggestion might be rather improved if the expense-magazines were to be built partly under the respective ramparts; thereby becoming mines on occasion. (See *Plate I. Tactics, fig. 4.*)

Against works of masonry built upon the terre-pleine, we cannot too powerfully inveigh: the immense numbers of splinters which are generally created by such being sufficient grounds for their condemnation. If, however, it is deemed proper to have small magazines in such situations, (for there may be localities which afford no alternative,) such ought to be sunk so far as to allow the summits of their arches to be little more than level with the terre-pleine. Being then covered with soil, and well gazoned, (*i. e.* turfed,) they would become useful, by causing such shots as might be sent over the epaulement to throw up, instead of allowing them to trundle along the terre-pleine. (See *ENFILADE.*)

The entrances of all magazines of this description ought to be towards the back of the battery, and certainly might be rendered safer by making a few steps down upon the inner revetement; so as completely to cover not only the magazine itself; but the persons who might be employed to hand up the cartridges. (See *fig. 5.*)

*EXPENSIS Militum Levandis*, in *Law*, was a writ anciently directed to the sheriff, for levying allowance for the knights of parliament. See *PARLIAMENT*, and *REPRESENTATIVE*.

*EXPENSIS militum non levandis*, &c. an ancient writ to prohibit the sheriff from levying any allowance for knights of the shire upon those that hold lands in ancient demesne. *Reg. Orig.* 261.

*EXPERIENCE*, a kind of knowledge acquired by long use without any teacher.

Experience consists in the ideas of things we have seen or read, which the judgment has reflected on, to form for itself a rule or method.

Authors make three kinds of experience: the first is the simple uses of the external senses, whereby we perceive the phenomena of natural things, without any direct attention thereto, or making any application thereof.

The second is, when we premeditatedly and designedly make trials of various things, or observe those done by others, attending closely to all effects and circumstances.

The third is that preceded by a fore-knowledge, or at least an apprehension of the event, and determines whether the apprehension were true or false; which two latter kinds, especially the third, are of great service in philosophy.

Dr. Campbell, in his "Philosophy of Rhetoric," (vol. i. p. 129, &c.) investigates the nature and origin of experience; and observes, that those sources in our natures which give being to it, and consequently to all those attainments, moral and intellectual, that are derived from it, are sense and memory. The senses, both external and internal, are the original inlets of perception; and the articles of information exhibited by them are devolved on the memory. As remembrance instantly succeeds sensation, the memory becomes the sole repository of the knowledge received from sense; and hence it is the only original voucher extant of those past realities for which we had once the evidence of sense.

In order to render the knowledge thus acquired and preserved useful to us, in discovering the nature of things and regulating our conduct, a further process of the mind is necessary, and this is association. This retention and association are called experience. We may here observe, that though memory gives birth to experience, which results from the comparison of facts remembered, the experience, or habitual association, remains, when the individual facts on which it is founded are all forgotten. We cannot pursue the reasoning of this ingenious writer in his illustration of the evidence of experience, which he considers as one species of moral evidence, (analogy and testimony being the two others,) and which, in his opinion, is the criterion, if not the foundation, of all moral reasoning whatever, and the principal organ of truth in all the branches of physiology, in the largest acceptation of the term. See *TESTIMONY*.

*EXPERIMENT*, from the Latin *experimentum*, is a trial, or practical proof of something. In philosophy it means the result of certain applications, dispositions, or combinations, of natural bodies, made with some particular view. Experiments are said to be mechanical, or chemical, or electrical, or magnetical, &c. according to the subject to which they more immediately belong. The object of making experiments is to ascertain either certain causes or certain phenomena; and for the proper attainment of these objects care must be had to institute experiments that admit of no equivocal result, and so as to answer the purpose in the quickest and most direct way. The main object, however, of the inquiry can seldom be determined by a single decisive experiment; hence, in most cases, it becomes necessary to divide the question into parts, and to ascertain each part separately by one or more appropriate experiments. When the experiment is so prescribed as to decide the question without any possible doubt or equivocation, it has in that case frequently been called *experimentum crucis*; meaning a capital or decisive experiment; such as supercedes the necessity of instituting more experiments for the same purpose. The origin of the expression *experimentum crucis* has probably been derived from its being a kind of torture, whereby the nature of the question is, as it were, extorted by force. It has been also attributed, though with less apparent probability, to the guide or instruction which it affords, like that of a direction post, which is shaped somewhat like a cross.

It is not practicable to give any instructions for the right performance of experiments in general; for not only every subject, but every particular question belonging to any subject, must be determined by a peculiar mode of investigation. The experimenter can only be instructed by practice. The nature of the subject, a strict attention to every apparent circumstance, an accurate statement of particulars, and an unprejudiced mode of reasoning, will easily suggest a proper train of experiments which the subject in question may admit of. It deserves to be remarked, that though in the investigation of any subject, the philosopher proposes a certain order of investigation, (and it is always proper to propose to oneself some such plan or train of experiments;) yet it is but seldom that the proposed plan can, or deserves to be strictly executed; for the result of the first or second experiment frequently points out a new track or a more promising road; in consequence of which, new and different trials must be instituted; and it is in the ready adoption of such plans as may be more suited to the last indications, that the genius of the philosopher is rendered conspicuous.

Such mode may suffice for the determination of any doubtful point; but when a discovery has been made and is to be explained

explained to other persons; then it is of use to shew the same result by different experiments; for it is not only a satisfaction to have several concurring proofs of the same proposition; but it is also rendered intelligible to a greater number of readers or hearers; it being seldom the case, that the same experiment conveys an equal degree of conviction and satisfaction to the mind of every body.

EXPERIMENTAL FARM, in *Agriculture*, that sort of farm establishment which is chiefly applied to, or calculated for, the purpose of making experiments, with the view of ascertaining unknown causes, effects, or results in the various departments of husbandry. This is a plan which has often been attempted, both individually and collectively, by numbers of persons warmly interested in promoting the improvement of agricultural knowledge; but hitherto, we believe, without that sort of success which might naturally be expected. The cause of which has probably been the want of a due combination of real practical agricultural information with that of the scientific kind, as without a full comprehension of both these, in persons who have the direction and management of such establishments, it must be utterly impossible that they can be so highly advantageous as they ought to be. But a writer, who has bestowed much attention on the subject, seems to suppose that, there is much doubt of any real benefit being at all produced in this way; as he considers both experience and experiment the two means by which facts concerning the art may be ascertained as equally liable to objection. The term *experience* he conceives to denote those deductions which a person draws as the average result of practice continued for a considerable length of time, and which is unquestionably the surest guide that can be followed, where the observations are sufficiently correct, and the circumstances discriminated in so clear a manner as to create no sort of confusion; still where these peculiarities are wanting, the conclusions thus drawn may be extremely fallacious. And what increases the evil in this case is, that when conclusions have been once drawn in consequence of an imperfect discrimination of circumstances, there is scarcely any chance of eradicating the error; as the mind, when once accustomed to think in a certain way, is apt to proceed in the same ever afterwards; and that the same indiscrimination which caused the first error will induce a succession of others of the same sort *ad infinitum*. Unfortunately, too, it happens that in agriculture, things which are capable of affecting the result of a process or operation, are so jumbled and thrown together into one chaotic mass, that it is a matter of extreme difficulty even for the most nice observer to distinguish such as are essential, from those which are merely accidental, consequently extremely easy to mistake one for the other. The inaccuracy likewise, which too much prevails in the operations of the farmer, concerning the actual expence of different processes, as affecting any particular object; and all the difficulty of keeping the different produce of different fields separate, render it, in most cases, almost impossible for the actual farmer to ascertain, with any sort of precision, either the expence or the value of the produce of any one of his fields; consequently the profit or loss of any operation or process is merely guessed at, not ascertained by the test of his experience; in consequence of which he is at liberty, and will of course draw the conclusion, which seems most to confirm his own pre-conceived notion on the head, whatever it may be. Under such circumstances experience must, he conceives, be a very fallacious and imperfect guide. It may, indeed, it is supposed, furnish hints or indications of what ought to be pursued or laid aside and avoided; but that un-

less facts be ascertained with much greater precision than it admits of, they must, it is conceived, afford a very unstable foundation for promoting the scientific improvement of agriculture.

In consequence of which, experiment, he thinks, has been introduced and adapted, in order to supply the deficiencies which are thus produced; but which, though, at the first sight, it may promise fair to accomplish such purposes, upon a nearer view has not been found adequate in any material degree. An experiment in this art is, it is conceived, a particular operation, undertaken with the design of elucidating and explaining some fact which is involved in doubt or difficulty; of course extreme accuracy, in order to guard against every circumstance that may unintentionally affect or influence the result, is an indispensable requisite in the conducting of it; as, unless this be the case, the same experiment, under different circumstances, may lead to a variety of conclusions. In general, however, farmers, from their having been but little accustomed to the nice discriminations of scientific investigation, are but indifferently qualified to guard against the secret influence of causes, which they have never even so much as suspected of having any power upon the result of their experiment. It is, therefore, contended, that from these causes the experiments made by actual farmers frequently prove extremely defective; and when amateurs of a higher rank project experiments, the detail of them must be left to servants and dependants, who commonly put down at random all the circumstances which their carelessness prevented them from noticing; so that these experiments, though they may assume a more engaging appearance of accuracy, are, in fact, for the most part, more inaccurate and erroneous than the former. Consequently, with the view of remedying these evils, the notion of an experimental farm has presented itself to many persons as the only means of forwarding the progress of scientific agriculture, and upon a slight view, the benefits that might result from it have indeed seemed so obvious, that in several districts of this country funds have been provided, as has been already hinted, for the support of such establishments, but on trial they have all found such difficulties in the way, as have not hitherto been capable of being surmounted. The chief reason of which, it is conceived, is, as has been suggested before, that of the difficulty of procuring a person in every way properly qualified for conducting such an undertaking. On these grounds, the expectations of the benefits that are to be derived from the establishment of an experimental farm are not by any means so great as may be supposed. It is, indeed, contended, that there are many experiments of the very first importance in scientific agriculture, which are totally out of, or beyond the sphere of a farm of this kind. Of this description, it is conceived, are all those facts which have a relation to the original constitution of soils, and the infinitely diversified, though little obvious qualities these possess in consequence of peculiar impregnations, which they may have derived from the operations of nature or of art. It is supposed that an experimental farm, in so far as this particular is concerned, is precisely the same as another farm, in which the experimenter, like the farmer, may in time acquire a knowledge of what will suit his own soil. But if these experiments were presented to the public under the idea that the results which they afforded should be deemed generally conclusive in all districts, such a decision would turn out fallacious, as it would soon be found, that, in many other cases, the results would be extremely different. Nor is it believed that the practical farmer could derive much advantage from the experimental farm, in what respects the

## EXPERIMENTAL.

economical distribution or arrangement of the necessary business which is to be pursued in the conducting of the work, which is a branch of the art that is of the greatest consequence to be well understood by the real farmer, but that is totally incompatible with the complex arrangements and continually varying operations of the experimental farm.

But however true many of these remarks may be, there can be little doubt, but that the establishment of experimental farms in different parts of the country must, under proper management, be attended with great advantage in throwing additional light on different branches and modes of cultivation, as well as in bringing agriculturists acquainted with a variety of new and interesting facts.

When conducted under a proper system of management, farms of this kind might readily ascertain the following important questions.

- 1st. What is the best mode of cultivating arable land?
- 2d. What is the best system for the management of grass land?
- 3d. What are the most useful implements of husbandry?
- 4th. What are the most profitable breed of animals, and the best, and cheapest modes of feeding and fattening them?
- and,
- 5th. What is the best plan for rendering waste or barren land productive?

All these questions are evidently to be considered in relation to the differences of soils, circumstances and situations.

Mr. Arthur Young, in speaking of the establishment of a farm of this nature, as being properly an undertaking only fit for a sovereign, in the fourth volume of his "Annals of Agriculture," remarks, that it would have great effects in promoting agriculture in this country, but in others, where that art is still less understood, it is absolutely essential to the progress of it. And that if, in some future age, this art, so necessary to the welfare of mankind, should receive an attention that has hitherto been denied it, and a farm of this sort should be established, the following hints may be found of use. It is conceived, that a divided attention to complex questions should be avoided; and those great leading objects most nearly connected with the deficiencies of the national agriculture demand the first exertions to ascertain. With this view the soil of the farm should regulate the plan of it. If it were a sand one in this country, it should, it is supposed, be thrown into the Norfolk husbandry, and the object of these experiments would be to examine how far that system, by means of carrots, turnip-cabbage, and other new plants, equi-distant drilling, manuring for the roots and grasses instead of the wheat, &c. could be improved. And connected with this inquiry would be the collateral one of the breed of sheep, proper for this soil; with other objects too numerous to recite, which are at present unascertained.

If the soil were of the clayey or loamy kind, too wet for turnips, the great objects would, it is supposed, be, the means of banishing summer fallows, an inquiry of great importance; the culture and use of cabbages; the modes of draining by hollow cuts and arched lands; the best means of converting such lands to meadows, and the proper breed of cattle.

And on a loamy soil, strongly inclining neither to clay nor sand, very interesting inquiries are to be pursued. Every plant, common on all other soils, is to be cultivated on this. The rotations of crops; the culture of potatoes and carrots, and their application to all sorts of cattle; lucerne, and its use in summer feeding a dairy of cows, that are supported in the winter on the roots, &c. are among the numerous inquiries

to be prosecuted on this sort of soil. On chalky soils the principal object is, it is supposed, the culture of saintfoin, and the best means of converting it to corn and turnips preparatory to a renewal.

But on a peat-moor many dubious points are to be ascertained; the best means of reclaiming, whether by paring and burning, fallow, or mere manuring. The grasses proper to lay down with; and the means by roots or cabbages, of supporting the greatest possible stock of that breed of cattle and sheep, which are found by experiment most proper for the soil; the method of draining, manuring, and giving solidity to bogs, &c. Upon all, or either of these soils, collateral inquiries would arise in relation to manures, tillage, instruments, &c. and a great variety of doubtful points to be decided in the culture and management of all the plants usually raised on any of them.

A small botanical garden of two or three acres, under a botanist, for small experiments upon plants not cultivated but promising; and a laboratory for chemical trials on soils, manures, and vegetables, would, it is suggested, be two necessary additions to such an establishment; and with a smith's and wheelwright's work-shop would render the whole complete.

The great features of such a plan would, it is supposed, be of utility; it would, however, be susceptible of no inconsiderable ornament. The lines of the inclosures might be decorated in any imaginable way, provided the contents of the field applicable to useful grass or corn were traced by right lines. Every tract of land, of a considerable extent, has some broken ground, steep slopes, water-courses in glens, or pieces where the plough cannot move with convenience, and where grass is not an equal object with more level spaces; these, by a judicious disposition of the ground, might be connected with the margins of the fields, and, by walks being traced through them, might be made highly ornamental and pleasing. It is suggested that one of Brown's winding walks, with its usual accompaniment of shrubs and velvet lawn, surrounding thirty, forty, or more acres of grass, is never seen, but it brings to the mind the variety such a space is capable of, by being thrown into experiments that yield a food for the mind as well as the eye. Some delicious spots, it is true, unite so happily in all their parts, melting by an easy gradation into so rich a harmony of distribution, that any change would offend as much as dissonance in a piece of pleasing music. But such spots are rare: in general, the variety of neat and elegant experiments would not injure the effect at all. The Leasfowes was, it is stated, in all its parts, a farm, and much more agreeable to the eye, than if the whole had been lawn. But in the present system of decorating ground, variety of effect is wanting; something to bring variations to the scene, in which the owner shall be interested: The lawn that was smooth yesterday is smooth to day, and the revolution of the seasons that bids the rose breathe its perfume in June, and wither in November, brings to the eye a succession of the same images which please this year, as they pleased the last, without novelty in the cause, or increase of pleasure in the effect. The highest decoration of landscape will not give it the power of variety; it will be the same this August as it was the last; it will be gay in summer; and dreary in December; its forcible effect is for others not yourself; for at every repetition of viewing the colours fade, and what once excited rapture, now brings no other emotion than cold approbation. The beauty of a mere garden-scene is like that of a fine face; it moves admiration at first, and we feel ourselves under the enchantment of a spell that chains all our senses; but let the enchantress speak, and prove herself a

## EXPERIMENTAL.

pretty fool, the inanity of her conversation breaks the spell, and she is from that moment less than a pretty picture, since no one claims a merit in making her. The beauty of a garden-scene is much of the same kind; it holds little conversation with you; it suggests no new ideas; it furnishes no food to an inquisitive mind. If a person be told that he may contemplate the works and wisdom of God; and hold converse with the vegetable and animal creation, he replies, not because he is in a garden, for a nettle is as wonderful a production of divine power as a lily, and the structure of a toad an object to philosophize on, as much as a nightingale. Hence the contemplative pleasures of a decorated scene are not appropriated; they arise from the parts and not the combination; and therefore, in this respect, might as well not be combined at all. But when the ornamented walks lead you to something that offers novel information with every season, when you are in the pursuit of unknown facts, to ascertain which is to promote not your own solitary pleasures and contemplations only, but a science intimately connected with the prosperity of a nation; when every inclosure is pregnant with instruction, the field of a pursuit, and consequently of a pleasure; in such a case, it is not a question of an arrangement of a lawn, and water, and shade, that shall please the eye for a time; it is not the bloom of a flower, or the bend of a walk, but a subject where the renovation of the year brings perennial employment for the mind: your landscape becomes the source of thought; the eye may be pleased, but the understanding is satisfied; and instead of modes of duration that have been repeated to satiety, a novel scene is created, at once the theatre of private pleasure and public instruction; where useful knowledge is sought, not in vain theories, and indolent speculation, but in the vigour and activity of experimental exertion. Compared with such an application of a tract of land, what are parks and gardens, shrubberies and decorated grounds, but so many baubles to please children; frivolous efforts to fill the eye, but leave the mind vacant. The prince that raises palaces, and embellishes the gardens that surround them, may be commended for his taste, and praised for his magnificence. Versailles was called a creation; but had Lewis XVI. established such a farm as has been described; had the experiments been registered and published for the benefit of France; how little would the reputation of that creation now be found, compared with the genuine and never dying fame that would have sprung from a different application of the same ground. The prince that rears a palace, does what princes have done before him; but he who founds an establishment for the instruction of his people in the most necessary of all arts, does that which none have done before him, and deserves a title more truly valuable than that of *Great*, so often ill applied to the destroyers, not the protectors, of humanity; he will enjoy the title of the "Friend of Mankind."

A late writer on modern husbandry, however, seems to think more favourably of this method of bettering the state of agriculture than the author mentioned above, as he considers it as a mean by which a general spirit for such improvements may be the most effectually introduced. It is a measure, he supposes, which there is every reason to believe would be attended with good consequences, in regard to the determining with exactness the proper quantities of the different sorts of manures that ought to be applied to the different kinds of soils; the sorts best adapted to each; and the effects they produce when applied singly or in their compound state. But the utility of public experimental farms in every county, if put under the direction and management of persons of extensive knowledge and experience, should

not, it is contended, be estimated by a reference to any particular branch: husbandry, in all its departments, would be greatly improved in this way; and should the period ever arrive when the obstacles that stand in its way shall be removed, and proper means be had recourse to, for diffusing a general knowledge of the best methods of conducting the various operations connected with that science, that which has been suggested must not be overlooked. It is supposed that such sorts of farms would become so many seminaries, at which youth might be instructed in the nature, principles, and practice of agriculture, and to which the common farmer might occasionally resort for information, in respect to the success of experiments made as it were under his own eye, and on soils, in situations similar to those of his own.

And the author of "Rural Economy of the Midland Counties," in speaking of the advantages of these sorts of farms, asks, "what man, whether of the superior class of yeomanry or tenants, or of a superior class of tradesmen or others, who are now bringing up their sons to husbandry, would not, after his son had gone through a course of private tuition, and received the rudiments of instruction from himself or some professional friend, wish to perfect his education in a public seminary; where he would have not only an opportunity of seeing practice in its highest state of improvement, and of conversing with professional men of the most enlightened understandings; but where he would be duly initiated in the theory of rural knowledge, in the method of making, registering, and observing the result of experiments; of ascertaining the inherent qualities, and improving the various breeds of live stock; where he would see order and subordination, and learn the proper treatment of servants; and among a variety of other branches of useful knowledge, the form and method of keeping farm-accounts, and of ascertaining with accuracy the profit or loss upon the whole, and every part of his business; consequently of bringing it, as nearly as in its nature it is capable of being brought, to a degree of certainty."

But whatever may be the opinion of some concerning the utility of public establishments of this nature, we are inclined to believe that they will be found more beneficial when under the direction and management of private individuals who are sufficiently qualified for such undertakings, for though they may be far less extensive, they will be much more usefully conducted from their being less subject to those improper checks and controuls, which are continually taking place when a number of persons are concerned.

*EXPERIMENTAL philosophy.* Pythagoras is said to have been the first person who called himself philosopher, viz. a lover of knowledge or wisdom, from the Greek words φίλος, a friend or lover, and σοφία, knowledge or wisdom; from which appellation the word philosophy was derived, meaning the love of general knowledge; and according as this knowledge relates to the manners, the duties, and the conduct of human beings, considered in a rational and social light, or to the phenomena of natural bodies, so it has been called either *moral philosophy* (from the Latin *mos* or *mores* its plural, which means *behaviour* or *manners*) or *natural philosophy*.

The philosophers of the primitive ages, among the Greeks, Romans, &c. in explanation of the phenomena of nature, such as the motions of the celestial bodies, the rain, snow, frost, thunder and lightning, the rainbow, the combustion of fuel, the production of animals and vegetables, and so forth, generally offered the inadequate suggestions of their imaginations, which, though mostly unintelligible, and frequently absurd in the greatest degree, were nevertheless received with deference by their scholars, and were propagated with

## EXPERIMENTAL.

with fidelity or diligence from one generation to another. Their acquiescence rested merely on the authority of the teacher. That these explanations were generally inadequate and absurd, is easily evinced by observing that different contemporary philosophers entertained and taught opinions diametrically opposite to each other, though they related to the very same question; and that subsequent philosophers have by actual observations, and unerring demonstrations, shewn their fallacy. It may amuse an inquisitive mind to observe, that whilst the exertions of the early mathematicians, whose productions have obtained the admiration of subsequent generations, were strictly rational and correct, the investigations of their contemporary philosophers were conducted in a manner altogether slovenly and superficial. This method of philosophising prevailed for a very long period, and in consequence of it several centuries elapsed, during which the knowledge of nature made no progress deserving of notice, excepting a few rare and accidental discoveries.

The 15th century, which was productive of the greatest events and the most consequential discoveries that history can record, seems to have given a new turn to the subject of natural philosophy. The old tenets began to be doubted, and the energies of the human mind began to manifest their unfettered powers. In the next century, the incoherent dogmas of the preceding ages were freely combated; the authority of names and sects was disregarded, and in lieu of opinions, the explanation of natural phenomena was referred to the evidence of actual experiments; and this introduced the appellation of *experimental philosophy*, meaning the knowledge of natural powers and natural effects, acquired by means of experiments or trials. The least reflection readily shewed the superiority of this new method of philosophising; but, independent of any other consideration, its establishment is principally due to the success with which it was attended, and which exceeded even the most sanguine expectations of its first promoters; for it was no sooner adopted, than discoveries of importance were made, old-established errors were detected, and the subject of philosophy assumed an entirely new aspect.

It is undoubtedly true, that in this mode of investigation the experiments must be preceded by hypothesis, or supposition; for a man cannot begin to make experiments without the previous formation of a certain plan; but then the plan, the supposition, or the hypothesis goes no farther than to propose something, the confirmation or refutation of which is referred to the result of experiments, assisted by mathematical calculation.

In the 13th century, the necessary preliminaries for the improvement of natural knowledge began to be made; *viz.* collections of what then prevailed under the denomination of scientific knowledge, natural knowledge, secrets of nature, and the like; and the farrago of truths, errors, inconsistencies, doubts, and perplexities, which these works contain, is strange indeed. Among the few who effectually began to work in the experimental mode of investigation, during that century, friar Bacon held the most distinguished place. His desire of information was great; his views extensive; his mind clear and capacious; and he is said to have spent about 200*l.* (a sum very considerable at that time) in the performance of his numerous philosophical experiments. Baptista Porta also distinguished himself for similar pursuits in Italy. This inquisitive person lived at Naples, and about the year 1560 formed a society of scientific persons, who met in his own house. The great Galileo, who was born in Italy in the year 1564, became famous as a philosopher and a mathematician towards

the latter end of that century and the beginning of the next. His genius, superior to the prejudices of the times, investigated and established several leading propositions in natural philosophy; and his success, his example, and his precepts disseminated an universal ardour for the true mode of investigating the powers and the effects of natural bodies. His successor, Torricelli, was not unworthy of a most distinguished rank amongst the philosophers of the age; and the Torricellian tube, or the barometer, is a magnificent monument of his experimental inquiries.

In England, as we have already mentioned, friar Bacon was the first promoter of true knowledge; but a great part of the work of philosophical reformation was accomplished by another inquisitive genius of the same name. Francis Bacon, lord chancellor of England, gave a fresh and vigorous impulse to the progress of experimental enquiry. He recorded a vast number of facts, proposed and executed a great many experiments; and nothing that related to nature seemed to be below his notice.

These early reformers of philosophy, besides other obvious difficulties, were obliged to struggle against, and the success of their labours was much impeded by, the wrong notions which then prevailed, and which had been long rooted in the minds even of the most able persons then living. Galileo was nearly oppressed by the ignorance and prejudices of the clergy. Crichton, who flourished about the latter end of the 16th century, wrote an able book expressly against the vain philosophy of Aristotle, which had long been read in the schools. The two Bacons, and other able writers, frequently allude to, and strenuously endeavour to remove, the wrong notions of their contemporaries, and, in short, the demolition of the old defective fabric, proved nearly as laborious as the erection of the new structure.

The reform which had been begun by the above-mentioned and other worthy persons was soon after completed by the extraordinary genius of Newton. This truly great man, like a luminary of the first magnitude, illustrated whatever came within the limits of his notice, and his notice was employed in the greatest and most admired works of the creation. His method was to institute experiments, to examine the phenomena with accuracy, and to ground upon them the strictest mathematical reasoning. The conviction which such rational method conveyed, and the numerous discoveries with which it was attended, completely exploded the old tenets, and established the only true method of investigating nature.

The progress of experimental philosophy might have been interrupted by the death of a single individual; for it does but seldom occur that genius, health, opulence, and other opportunities concur in the qualification of an experimental philosopher; but the danger was in great measure averted by the institution of philosophical societies, which, by uniting the efforts of several ingenious labourers, by furnishing in great measure the means of investigation, by encouraging improvements, and by recording and propagating the results, have established the progress of knowledge in a regular and permanent channel.

The first society of the kind which we find recorded, is that which we have already mentioned at the house of Baptista Porta in Naples, towards the latter end of the 16th century. It was called "Academia Secretorum Naturæ." Next to this, and before the end of the same century, the Academy, called of the Lyncei, was founded at Rome, and was rendered famous throughout the world principally by the renown of one of its members, the great Galileo. The Academy del Cimento, and several other associations of scientific persons, were established in the succeeding, *viz.*

## EXPERIMENTAL.

the 17th century. And amongst those associations the first rank must be assigned to the Royal Society of London. This most learned and distinguished society had its origin soon after the middle of the 17th century. A few men of learning began to meet at stated times in Wadham college, Oxford; and among those persons there were the following conspicuous characters; *viz.* Dr. Ward, Robert Boyle, Dr. Wilkins, sir William Petty, Mr. Matthew Wren, Dr. Wallis, Dr. Goddard, Dr. Willis, Dr. Bathurst, Dr. Christopher Wren, and Mr. Rooke. From Oxford this association transferred its meetings to Gresham college in London, which took place in the year 1658. There they increased their number, and soon after the restoration of Charles II. that society received a royal charter, which established it into the form that has been continued ever since; but we must refer the reader to other articles of this Cyclopædia for the particular account of the Royal Society of London, as well as of other scientific associations in this and other countries; and at the same time we must proceed to explain the new mode of philosophizing in a manner somewhat more particular.

The objects of the universe, or the natural bodies, which affect our senses, become known and useful to us by their properties, some of which affect one of our senses, whilst others affect some other sense. Thus we perceive luminous bodies through our eyes, sound through our ears, heat or cold by the touch or feel, &c. Some of these properties are called general, like gravity and extension, because they belong to all bodies; and others, like transparency and fluidity, are called particular, because they belong to certain bodies only. The better we become acquainted with the properties of natural bodies, the more extended the sphere of our powers and of our advantages becomes; and it is for the discovery of these properties, either in simple or in compound bodies, that experimental inquiries are instituted.

In the acquirement of knowledge, the human being has no other assistance besides that of his senses, and of his reasoning faculty. By the first he observes and acquires ideas of self evident propositions, or properties of natural bodies; such as the human mind cannot dissent from without manifest violence; by the second he is led from one of these evident simple propositions, to another strictly depending upon the first, then to a third strictly depending upon the second, and so on, to the acquisition of some idea more complex, and less apparent at the first annunciation.

The constant observations of philosophers, with sir Isaac Newton at their head, and the dictates of plain reasoning, have furnished certain axioms and certain rules of philosophizing, the propriety of which is too evident to be objected to.

The axioms of philosophy, or the axioms which have been deduced from common and constant experience, are so evident, and so generally known, that it will be sufficient to mention a few of them only.

1. Nothing has no property; hence
2. No substance, or nothing can be produced from nothing.
3. Matter cannot be annihilated, or reduced to nothing.

The propriety of the last axiom may perhaps be not readily admitted by certain persons; observing that a great many things appear to be utterly destroyed by the action of fire; also that water may be caused to disappear by means of evaporation, and so forth. But it must be observed, that in these cases the substances are not annihilated; they are only dispersed, or removed from one place to another, and by being divided into particles very minute, they elude our

senses, and escape our immediate notice. Thus, when a piece of wood is placed upon the fire, the greatest part of it disappears, and a few ashes only remain, the weight and bulk of which do not amount to the hundredth part of the weight and bulk of the original piece of wood. In this case the piece of wood is divided into its constituent principles, which the action of the fire drives different ways. The fluid part, for instance, becomes steam, the light coaly part either adheres to the chimney, or is dispersed through the air, &c. so that if, after the combustion, the scattered materials were collected, (which may in great measure be accomplished,) the sum of their weights would equal the weight of the original piece of wood.

4. Every effect has, or is produced by, an adequate cause, and is proportionate to it.

It may in general be observed, with respect to these axioms, that we only mean to assert what has been constantly shewn, and confirmed by experience, and is not contradicted either by reasoning or by any known experiment. But we do not mean to assert that they are as evident as the axioms of geometry; nor do we in the least presume to prescribe limits to the agency of the Almighty Creator of every thing, whose power and whose ends are too far removed from the reach of our understandings.

Having thus stated the principal axioms of philosophy, it is in the next place necessary to mention the rules of philosophizing, which have been formed, after mature consideration, for the purpose of preventing errors as much as possible, and of leading the student of nature along the shortest and safest path to the attainment of true and useful knowledge. These rules are not more than four; *viz.*

1. We are to admit no more causes of natural things, than such as are both true and sufficient to explain the appearances.
2. Therefore to the same natural effects we must, as far as possible, assign the same causes.

3. Such qualities of bodies as are not capable of increase or of decrease, and which are found to belong to all bodies within the reach of our experience, are to be esteemed the universal qualities of all bodies whatsoever.

4. In experimental philosophy we are to look upon propositions collected by general induction from phenomena, as accurately or very nearly true, notwithstanding any contrary hypotheses that may be imagined, till such time as other phenomena occur, by which they may either be corrected, or may be shewn to be liable to exceptions.

With respect to the degree of evidence which ought to be expected in natural philosophy, it is but proper to remark that physical matters are not in general capable of such absolute certainty as the branches of mathematics. The propositions of the latter science are clearly deduced from a set of axioms so very simple and evident, as to convey perfect conviction to the mind; nor can any of them be denied without a manifest absurdity. But in natural philosophy we can only say, that because certain particular effects have been constantly produced under certain circumstances, therefore they will most probably continue to be produced as long as the same circumstances exist; and likewise that they do, in all probability, depend upon those circumstances. And this is what we mean by *laws of Nature*; *viz.* certain effects which are or have been uniformly produced by certain causes, as far as our observations reach.

We may, indeed, assume various physical principles, and by reasoning upon them, we may strictly demonstrate the deduction of certain consequences. But as the demonstration goes no farther than to prove that such consequences must necessarily follow the principles which have been assumed; the

## EXPERIMENTAL.

the consequences themselves can have no greater degree of certainty than the principles are possessed of; so that they are true, or false, or probable, according as the principles upon which they depend are true, or false, or probable.

The foundations of experimental philosophy, as we have already observed, are the properties of natural bodies, *viz.* of all those bodies, either solid or fluid, which in any way affect any of our senses: and since our senses are affected by the properties of these bodies, *viz.* by their extension, colour, hardness, transparency, &c. we cannot know any more of these bodies than what is manifested to us by such properties only as we are able to perceive. Were we furnished with other senses, we might discover other properties which would make us more intimately acquainted with the nature of such bodies.

Human art has not been able to discover more senses than those which every body knows; but it has, in great measure, improved some of those which we possess, and this alone is sufficient to point out the limited nature of our perceptions. Thus, for instance, the discovery of the microscope, and the telescope, have shewn us wonders of which our forefathers were utterly ignorant; and the number and variety of these wonders have increased in proportion as the above-mentioned instruments have been improved. The improvements of these instruments have been suggested by the discoveries that have been made respecting the refrangibility of light, and the properties of transparent bodies, and these have been made in consequence of the innumerable experiments that have been instituted by various intelligent persons. Thus it appears, that by means of trials and observations new facts are ascertained, which, besides their being immediately useful to the human species, furnish, at the same time, the means of making farther discoveries; and the treasures of the natural world are far, indeed, from a state of exhaustion. Hence the improvements and the discoveries of experimental philosophy proceed in a kind of increasing geometrical progression; unless they be impeded by some extraordinary occurrence.

In contemplating the intimate nature of natural bodies, when our mind goes beyond the bounds of our senses, (and our senses, even with the assistance of instruments and reasoning, are only capable of perceiving a few properties of those bodies;) we wander in the boundless field of probability and conjecture. Two principal hypotheses have been entertained with respect to the primitive component particles of bodies. One is, that the particles of each peculiar species of bodies are different from the particles of another species of bodies. Thus the primitive particles of gold are supposed to be different from the particles of calcareous earth, different from the particles of water, &c. The other hypothesis is, that there is one kind of primitive or original particles of matter, and that from the different arrangement of these ultimate particles, the various bodies arise. Experience shews that certain bodies, which, at first sight, appear to be absolutely different from each other, are, upon further examination, exactly of the same nature. On the other hand, a vast number of bodies are so distinct from each other, that no art has been able to form one of them from the particles of another; thus gold cannot be converted into a diamond, iron cannot be converted into lead, &c. The former of these observations seems to favour the second hypothesis; the latter seems to favour the first hypothesis; but it is not in our power to determine the real state of the matter.

With respect to the number of bodies, which, by our not being able to change one of them into the other, are called elementary, or primitive and distinct, the reader will find

sufficient information under the article ELEMENT; but it may be remarked in this place, that new bodies are frequently discovered in proportion as new instruments, and the improvements of science in general, furnish us with the means of discriminating them from others; hence we are naturally led to conclude, that most probably there may exist a vast number of other bodies, of which we at present have not the least suspicion. Some of these may perhaps be discovered hereafter, whilst others may remain utterly unknown to the human species.

The properties of natural bodies, which are the objects of research to the experimental philosopher, are either general, or particular. The general properties, which belong to all kinds of bodies, are, as far as we know, not more than six; *viz.* extension, divisibility, impenetrability, mobility, vis inertiae, or passiveness, and gravitation. We have said that these are the general properties as far as we know, because matter in general may possess other properties that are not yet come to our notice. And the same observation may be made with respect to the universality of these properties: for they are said to be general, because no body was ever found which wanted any one of them. But mankind are not acquainted with all the bodies of the universe, and even several of those which are known to exist, cannot be subjected to experiments.

The peculiar properties, *viz.* those which belong to certain bodies only, and not to others, are density, rarity, hardness, softness, fluidity, rigidity, flexibility, elasticity, opacity, transparency, the properties of light, the properties of heat, the properties of electricity, the properties of magnetism, and three other kinds of attraction, (independent of gravitation, of electricity, and of magnetism,) *viz.* the attraction of aggregation, which the homogeneous parts of matter have towards each other, or by which they adhere together; and such is the power by which two small drops of mercury, when placed contiguous to each other, rush, as it were, into each other, and form a single drop; the attraction of cohesion, or that power by which the heterogeneous particles of bodies adhere to each other without any change of their natural properties, such as the adhesion of water to glass, of oil to iron, &c.; and the attraction of composition, or of affinity, which is the tendency that the parts of heterogeneous bodies have towards each other, by which they combine, and form a body, differing more or less from any of its components.

It is to be remarked, that of all these properties we know their existence only, and some of the laws under which they act; but we are otherwise utterly ignorant of their nature and dependence.

The investigation of some of the above-mentioned properties, whether general or particular, has been carried much farther than the investigation of other properties. The results of these investigations have likewise been various, both in point of extent and of application. Some of them are so very extensive and so useful, as to form the foundations of very important branches of science or of art, under peculiar appellations. Thus, upon the mobility and the vis inertiae of bodies, the doctrine of motion, or dynamics, is grounded, which comprehends mechanics, hydrostatics, or the mechanical properties of fluids, pneumatics, &c. Transparency and the properties of light form the important foundation of optics. The attraction of affinity is the foundation of chemistry, as well as of various arts, and so forth. Whatever belongs to these properties, or to the extensive subjects that are grounded upon the same, will be found under the various articles of their peculiar denominations.

The phenomena of the universe, are the appearances which take place in consequence of the above-mentioned properties of natural bodies, together (respecting some of them at least) with some original impulse. The phenomena which take place amongst the luminous celestial bodies, properly so called, such as the stars, the planets, &c. are examined by a particular science called astronomy; the meteors, or the phenomena, which take place within the limits of the terrestrial atmosphere, such as shooting stars, northern lights, halos, rain, fogs, hail, winds, &c. form the subject of meteorology. The phenomena that take place upon the surface of, or within, the earth, are treated of under the comprehensive denominations of *vegetation, earthquakes, volcanoes, combustion, &c.* all which will be found explained under their appropriate articles.

**EXPERIMENTUM CRUCIS**, denotes a capital, leading, or decisive experiment; thus called, either, because like a cross or direction post, placed in the meeting of several roads, it guides and directs men to the true knowledge of the nature of the thing they are enquiring after; or as it is a kind of torture, whereby the nature of the thing is, as it were, extorted by violence.

**EXPIATION**, the act of suffering the punishments adjudged to a man's crimes, and thus paying off, or discharging the debt or guilt; and it is figuratively applied to the pardon procured for the sins of the penitent by the interposition and death of Christ.

The Romanists hold, that souls after death are sent to purgatory to expiate or atone for their sins. See **PURGATORY**.

**EXPIATION** is also applied to sacrifices offered to the Deity, to implore his mercy and forgiveness.

**EXPIATION**, the *Feast of*, among the Jews, called by our translators the *day of atonement*, was held on the tenth day of Tisri, or the seventh month of the Jewish year, answering to part of our September and October. It was instituted by God himself, Levit. xxiii. 27, &c. On that day the high-priest, the figure or type of Jesus Christ, entered into the most holy place, and confessed his sins; and, after several ceremonies, made an atonement for all the people to wash them from their sins. Lev. chap. xvi. See **SCAPE-GOAT**.

**EXPIATION**, among the *Heathens*; denoted a purification used for effacing or abolishing a crime, averting any calamity; and on a thousand other occasions, as purifying towns, temples, and sacred places, and armies, before and after battle.

It was practised with divers ceremonies: the most usual was ablution.

Expiations were performed for whole cities as well as particular persons. After the young Horatius had been absolved by the people for the murder of his sister, he was farther purified by several expiations prescribed by the laws of the pontifices for involuntary murders. Dion. Halicarnass.

**EXPILATION**, from *expilo, I rob*, in the *Civil Law*, the act of withdrawing or diverting something belonging to an inheritance, before any body had declared himself heir thereof.

This made a peculiar species of theft; for there could not properly be a theft in taking a thing not possessed by any body, or before the inheritance was accepted.

For this reason the Roman legislature introduced the action of expilation for the punishment of this crime.

Beside this meaning, it was used in a more special manner to signify a robbery committed by night; whence an

expilator was looked upon as a greater criminal than a common thief.

The expilators were so called from their robbing and stripping people of their cloaths.

**EXPIRATION**, in *Physiology*, is the act of expelling air from the lungs, produced by a diminution of the cavity of the chest. It is opposed to inspiration, in which air is drawn into the chest. See **RESPIRATION**.

**EXPIRATION** is also used figuratively, for the end of a term of time granted, or agreed on, or adjudged.

**EXPLEES**, in *Law*, the rents or profits of an estate, &c. See **ESPLEES**.

**EXPLICATION** of the *Subject of a Discourse*, in *Pulpit Oratory*, and in the composition of sermons, comes in the place of narration at the bar, and should be conducted in a similar manner. It should be concise, clear, and distinct, and in a style correct and elegant, rather than highly adorned. To explain the doctrine of the text with propriety, to give a full and perspicuous account of the nature of that virtue or duty which forms the subject of the discourse, is properly the didactic part of preaching; on the right execution of which much depends for all that comes afterward in the way of persuasion. The great art in succeeding in it is, to meditate profoundly on the subject, so as to place it in a clear and strong point of view. Consider what light other passages of scripture throw upon it; consider whether it be a subject nearly related to some other from which it is proper to distinguish it, consider whether it can be illustrated to advantage by comparing it with, or opposing it to, some other thing; by enquiring into causes, or tracing effects; by pointing out examples, or appealing to the feelings of the hearers; that thus a definite, precise, circumstantial view may be afforded of the doctrine to be inculcated. Let the preacher be persuaded, that by such distinct and apt illustrations of the known truths of religion, it may both display great merit in the way of composition, and, what he ought to consider as far more valuable, render his discourses weighty, instructive, and useful. Blair's *Lectures*, vol. ii. p. 297.

**EXPLICATIVE PROPOSITION**, in *Logic*. See **COMPLEX Proposition**.

**EXPLICITE**, in the *Schools*, something clear, distinct, formal, and unfolded.

The will or intention is said to be explicite when it is fully explained in proper terms; and implicite, when it is only to be learnt by deductions and consequences.

The Jews had not all an explicite knowledge of Jesus Christ, but they had at least an implicite one.

Such a testator has declared his will explicitly, *i.e.* in formal terms; there is no need to have recourse to explanations.

**EXPLOITS**, *BAY of*, in *Geography*, a bay of the Atlantic, on the east coast of Newfoundland. N. lat. 49° 45'. W. long. 55° 20'.

**EXPLOSION**. It is a matter of great moment, in military engineering, so to load, and indeed to construct, a mine, that it may explode with the greatest precision, and with the maximum effect. A variety of theories has been given upon this subject, but it would be out of place to notice the whole of what appertains thereto in this place; therefore we shall refer our readers to the word **MINE** for the particular detail of what relates to this subject, contenting ourselves with now offering a few remarks on the manner in which the explosion is usually effected.

It is of the first importance to ascertain, so nearly as may be practicable, what depth, and what weight of soil is to be removed by an explosion. This being done, the mine is

## EXPLOSION.

formed, by a gallery leading to the chamber in which the powder is to be deposited in a very strong chest, let into a recess, and firmly secured in every part. Now, it being the nature of the rarefied air to escape by that part which may be the weakest, it is evident, that if a mine is made under a rampart, so as to be within six feet of the surface, while all the sides are thicker by far than that measurement, the explosion will be directed towards that part which is thinnest, and which from that circumstance is called "the line of least resistance."

But, in order to direct the explosion to that part, it will be necessary to consider whether the soil be every where alike; for if the superincumbent portion should be part of a large stratified rock, while the sides are of a loose, inadhesive substance, the latter, though measuring more in diameter, will give the line of least resistance, which, in such case, would follow the intencity, and create a false explosion. Hence explosions may be lateral as well as vertical.

It was formerly supposed, that the diameter of the entonnoir, or explosion, was equal to double the line of least resistance; but we find that *six times* that line may be exploded, by allowing a load of 300lbs. of gun-powder, duly concentrated, and fired in the middle of the mass, for every foot of the line of least resistance. We are not to infer from this, that 300lbs. will be requisite to lift one foot of soil; far from it; for as a cubic foot of excavation will contain only 75lbs. of powder, the above quantity (300lbs.) would require a space of exactly four cubic feet; the proportion would therefore be preposterous. But when we calculate upon large masses of soil, such as those prodigious cones thrown out from entonnoirs of great extent, we then find, that, to produce the completest explosion, an immense quantity of powder must be supplied.

It is self evident, that the power of the powder, according to the above scale, is only computed to that extent which may be necessary towards the ordinary purposes of military devastation; for if we were to contribute, *ad infinitum*, 300lbs. of gunpowder for every foot in the line of least resistance, we should be accumulating power only in arithmetical proportion, while the resistance would be increasing in a geometric ratio: of course the power must be in a regular state of comparative diminution, in proportion as the line of least resistance is increased; and this must, after a while, occasion the powder to be inert; or, if there should be any explosion, it could only follow the track of the train; its ignition to be sure might be felt partially, like that of a slight earthquake, but no superficial effects would be observable.

It has been already stated, that the powder must be lodged in bulk; and that it should be ignited at the centre. This may, perhaps, appear superfluous; but all military men know, that much powder is blown out of the muzzles of pieces without ever being ignited; and we have a most remarkable fact, a very recent one indeed, which shews that, unless in bulk; powder is not always sure to be fired *in toto*. The incident alluded to is as follows.

In the month of March of this year, (1809,) a barge was proceeding along the new cut, from Paddington, laden with casks of spirits and barrels of gunpowder. One of the crew, it is supposed, allured by the former, bored a hole for the purpose of drawing off a little wherewith to tipple. Unhappily the action of the gimblet set fire to the contents of that barrel, which the dishonest navigator had mistaken for one of spirits. The barrel exploded; and drove eleven other barrels, filled with gunpowder also, to the distance of near a hundred and fifty yards. It is curious, that

although the whole of the powder-barrels were together, indeed in contact, only that in question exploded.

Vauban gives us the following scale for exploding soils of various descriptions. He calculates, or perhaps found from experience, that for a cubic fathom (six feet) of soil, measuring in all 216 solid feet, the following proportions of gunpowder were needful.

1. Light earth, mixed with sand,	-	11lb.
2. Common earth	- - -	12
3. Strong sand	- - -	15
4. Clay, or fat earth,	- - -	16
5. Old, and good masonry	- - -	18
6. Rock	- - -	20

In following this calculation, we are to consider the entonnoir to be in diameter equal to only double the line of least resistance; and not according to a maximum explosion.

EXPLOSION, from the Latin *explodo*, is the act of driving out something with noise and violence. The causes, the report or noise, and the other effects of explosions, however insignificant they may appear at first sight, are nevertheless, when duly considered, of great consequence to the human species, and as such they have been carefully inquired into by divers philosophers. A variety of experiments have been instituted for determining the particulars that relate to them, and numerous conjectures have been offered in explanation of these concomitant circumstances, which have not as yet been thoroughly investigated.

Explosions may be distinguished into natural and artificial. The principal natural explosions are those of the atmospheric thunder, of volcanoes, of earthquakes, and to these there may be added the inferior explosions arising from hard frosts. The artificial explosions are such as are produced by the force of fired gunpowder in the various engines in which it is used, the explosions produced by other chemical compounds, and the pneumatic explosions; meaning those which are produced by the air rushing into a partial vacuum, by the discharge of air-guns and the like.

Of all these kinds of explosions we shall now briefly treat, not in the order in which they have been enumerated, as this would prove a useless formality; but in a manner which may be more likely to elucidate the most interesting part of the subject; and this undoubtedly is the stupendous force with which effects, in great variety, are produced in certain explosions.

The first thing that strikes the observer is the sudden and violent noise of an explosion. It is hardly necessary to observe that this noise or report is owing to the intermediation of the air between our ears and the cause, whatever that may be, of the percussion which is given to the air. Without that intermediation, or without air, the report could not be heard. But it must be farther observed, that the mere introduction of something into the ambient air is not the principal cause of the report. That effect principally depends upon the sudden replacing or collapsing of the air, after its having been removed or rarefied in any particular place. So that in order to account for the immediate cause of the noise in an explosion, we must look out for something which after having been introduced into the atmosphere, whether slowly or quickly, is afterwards *suddenly* withdrawn or contracted. A few examples will easily illustrate this observation.

Take a common syringe, stop the aperture of it, then draw the piston entirely out of its other extremity, and at that moment a report is heard, which is occasioned by the replacing of the air within the syringe; for in drawing the piston out of it, the air within the cavity of the syringe is rarefied,

## EXPLOSION.

rarefied, *viz.* a partial vacuum is formed, but as soon as the piston is quite out, the air of the atmosphere suddenly rushes in to supply that deficiency, and produces the noise or the report.

There is an experiment commonly shewn with the air-pump, and a glass vessel open at both ends. To one of the apertures of the glass vessel a wet piece of bladder is tied, and is suffered to become dry. The other aperture of the glass vessel is then placed upon the plate of the air-pump. This done, the air is extracted by working the pump, by which means the glass vessel covered over with the bladder is partially exhausted, and of course the pressure of the atmosphere is in great measure removed from the under surface of the piece of bladder. The atmosphere, then pressing on the upper part of the bladder, and not being counteracted from below, distends the bladder towards the cavity of the vessel, and at last breaks it with a considerable explosion. The reason of which noise is the sudden rushing in of the air.

An air-gun, when discharged, produces a trisling noise, the reason of which is, that after the expulsion of the condensed air from the inside of the instrument, which is impelled against the ambient air, there is no collapse of the latter; for the condensed air, on coming out of its confinement, expands itself to the tension of the ambient air, and remains in that state; *viz.* without any subsequent contraction.

There are little glass balls, containing a small quantity of water, which are made and sold for diverting experiments, under the name of *glass granades*. A ball of this kind is nothing more than a diminutive glass bottle partially filled with water, and having a longish neck or tail, hermetically sealed. One of these little bottles is stuck with its tail into the tallow or wax of a burning candle, and so that the little ball may be in the flame of the candle. In this situation the heat of the flame converts part of the fluid within the ball into vapour, and when the elasticity of this vapour is sufficient to overcome the resistance of the glass the ball breaks, and produces a smart explosion. The reason of which is, that the condensed vapour, on coming out of the glass, displaces a considerable quantity of air, but being instantly cooled, it contracts, and the air collapses.

A musket loaded with gunpowder, on being fired off, produces a strong explosion. Now the difference between the discharge of such a musket and that of an air-gun is, that though in both an elastic fluid is discharged; yet in the musket the elastic fluid contracts immediately after its coming into contact with the external air: but with the air-gun, the elastic fluid which issues out of it does not contract after its expulsion; hence the report is incomparably louder with the former than with the latter.

An electric spark, especially in the discharge of a Leyden phial or battery, is accompanied with a smart report, in consequence of its suddenly displacing the air from the spot in which it explodes; and of the subsequent collapsing of the air. And that the electric spark really displaces the air, is easily shewn by means of an electrical instrument, called "Kinnorsley's electrical air thermometer." In this instrument the spark is taken into a close glass vessel, which by an annexed narrow tube, partially filled with a liquor, indicates the rarefaction or displacing of the air within the vessel. With this apparatus, whenever a spark or discharge of an electric jar is taken within the close vessel, the rising and falling of the liquor within the annexed tube shews that the air is suddenly displaced, and is likewise heated in some degree; for the liquor rises suddenly to a certain degree; and as suddenly descends, not quite to its former station, but to a place a little above it, from which afterwards it descends gently to its original station.

From these facts, and from a vast many more which might here be described, it clearly appears that the sudden introduction of something into the ambient air produces little noise; but that the noise of an explosion is mostly due to the collapsing of the air, which takes place in consequence of the instantaneous contraction of that which has been introduced in it. The noise, *ceteris paribus*, is more or less loud in proportion as a greater or lesser quantity of air is displaced and replaced, and likewise in proportion to the quickness of that operation.

When more reports than one are heard; these are produced either by an equal number of explosions, or by a reverberation, *viz.* by an echo.

The air thus agitated conveys the sound of an explosion, or propagates its own vibrations, to immense distances. The firing of heavy ordnance has been sometimes heard at the distance of 50 or 60, and even more miles. The explosions of volcanoes, or those which accompany earthquakes, have often been perceived at distances much more considerable; but with respect to the extent of this kind of communication, rate of moving, &c. the reader is referred to the article *SOUND, propagation of, and HEARING*. We shall, however, in this place, briefly mention an effect of this kind of violent aerial vibration: which it might be wished that such persons as are opportunely situated, would examine with particular attention. The phenomenon is, that the explosion of cannons, and especially of powder magazines, or powder mills, renders the air considerably electrified, and that it electrifies the glasses of windows.

After the noise, or the report, the next step is to inquire into the cause or causes which produce it: *viz.* into the nature of the elastic fluid which, in coming out of any confinement, displaces the circumambient air, and then suddenly gives way to it. Until very lately the immediate cause of most explosions was principally attributed to the generation or extrication of permanently elastic fluids, *viz.* gases; and this is undoubtedly true in a great many cases; but upon a closer examination of the concomitant particulars, the expulsion of these elastic fluids, even in a state of incandescence, was found inadequate to the effects that were experienced in a variety of cases; hence philosophers began to look out for some other agent more active; and though the force of steam was known to be concerned in some kinds of explosions; yet it must be acknowledged, that we are indebted to count Rumford for a masterly examination of this particular point; for which purpose he instituted a long and laborious series of well contrived experiments. His account at large under the title of "Experiments to determine the Force of fired Gunpowder," is contained in the *Phil. Transf.* for the year 1797, and from that account we shall extract such particulars as may seem sufficiently to illustrate this important part of the subject of explosions. We call it important, because it is the particular from which the causes of natural explosions, such as of volcanoes, earthquakes, &c. may be obviously manifested.

Count Rumford justly says, "The explosion of gunpowder is certainly one of the most surprising phenomena we are acquainted with, and I am persuaded it would much oftener have been the subject of the investigations of speculative philosophers, as well as of professional men, in this age of inquiry, were it not for the danger attending the experiments; but the force of gunpowder is so great, and its effects so sudden and so terrible, that, notwithstanding all the precautions possible, there is ever a considerable degree of danger attending the management of it."

Several able philosophers had, at different times, endeavoured to determine the force of it. "But," count Rum-

## EXPLOSION.

ford says, "the great desideratum, the real measure of the initial expansive force of inflamed gunpowder, so far from being known, has hitherto been rather guessed at than determined; and no argument can be more convincing to shew our total ignorance upon that subject, than the difference in the opinions of the greatest mathematicians of the age, who have undertaken its investigation."

The ingenious Mr. Robins thought, that the force of the elastic fluid, which is generated in the combustion of gunpowder, is 1000 times greater than the mean pressure of the atmosphere. Mr. D. Bernoulli reckoned it equal to 10,000 times that pressure.

Count Rumford, in one of his first experiments, confined gunpowder in a strong iron tube, and fired it by heating part of the tube, or rather of an appendage that had been fixed to it. This was done with a view of confining the elastic fluid, that was generated in the combustion. "The result," he says, "of this experiment fully answered my expectations. The generated elastic fluid was so completely confined, that no part of it could make its escape. The report of the explosion was so very feeble, as hardly to be audible: indeed it did not by any means deserve the name of a report, and certainly could not have been heard at the distance of twenty paces; it resembled the noise which is occasioned by the breaking of a very small glass tube."

And farther on, he says, "It has generally been believed, after Mr. Robins, that the force of fired gunpowder consists in the action of a permanently elastic fluid, similar in many respects to common atmospheric air: which being generated from the powder in combustion, in great abundance, and being, moreover, in a very compressed state, and its elasticity being much augmented by the heat, (which is likewise generated in the combustion,) it escapes with great violence, by every avenue; and produces that loud report, and all those terrible effects which attend the explosion of gunpowder."

"But though this theory is very plausible, and seems upon a cursory view of the subject to account in a satisfactory manner for all the phenomena, yet a more careful examination will shew it to be defective. There is no doubt but the permanently elastic fluid generated in the combustion of gunpowder, *assists* in producing those effects which result from its explosion; but it will be found, I believe, upon ascertaining the real expansive force of fired gunpowder, that this cause, alone, is quite inadequate to the effects actually produced: and that, therefore, the agency of some other power must necessarily be called in to its assistance."

This author then proceeds to describe a variety of experiments and calculations which prove, beyond a doubt, that the above-mentioned theory is insufficient to account for the effects which are produced by the inflammation of gunpowder; for he computes, in the amplest manner possible, the force of the gas which is generated even in the heat of red-hot iron, by which elevation of temperature air is known to be expanded not much above four times its ordinary bulk. He endeavoured to measure the force in question by the lifting up of a very great weight, and his ingenious experiments were attended with results sufficiently satisfactory; but we must refer the reader to the above-mentioned paper itself for the detail of these interesting particulars; and we must here only add an abridgment of the latter part of the account, which more immediately relates to the principal object of our present enquiry.

"I will finish," the Count says, "this paper by a computation, which will shew that the force of the elastic fluid generated in the combustion of gunpowder, enormous as it

is, may be satisfactorily accounted for upon the supposition that its force depends *solely* on the elasticity of watery vapour or steam.

"It has been shewn by a variety of experiments made in England, and in other countries, that the elasticity of steam is redoubled by every addition of temperature equal to 30 degrees of Fahrenheit's thermometer.

"Supposing now a cavity of any dimensions (equal in capacity to one cubic inch for instance) to be filled with gunpowder, and that on the combustion of the powder, and in consequence of it, this space is filled with steam (and I shall presently shew that the water existing in the powder *as water* is abundantly sufficient for generating this steam); if we know the heat communicated to this steam in the combustion of powder, we can compute the elasticity it acquires by being so heated.

"Now it is certain that the heat generated in the combustion of gunpowder cannot possibly be less than that of red-hot iron. It is probably much greater, but we will suppose it to be only equal to 1000 degrees of Fahrenheit's scale, or something less than iron visibly red-hot in day light."

"As the elastic force of steam is just equal to the mean pressure of the atmosphere, when its temperature is equal to that of boiling water, or 212° of Fahrenheit's thermometer, and as its elasticity is doubled by every addition of temperature equal to 30 degrees of the same scale, with the heat of 212° + 30° = 242° its elasticity will be equal to the pressure of two atmospheres; at the temperature of 242° + 30° = 272° it will be equal to four atmospheres, &c.

"Following up our computations on the principles assumed, (and they are founded on the most incontrovertible experiments,) we shall find that at 692° + 30° = 722°, the elasticity will be equal to the pressure of 131,072 atmospheres, which is 130 times greater than the elastic force assigned by Mr. Robins to the fluid generated in the combustion of gunpowder; and about *one-sixth* part greater than my experiments indicated it to be.

"But even here the heat is still much below that which is most undoubtedly generated in the combustion of gunpowder. That the elasticity of steam would actually be increased by heat in the ratio here assumed, can hardly be doubted; it has absolutely been found to increase in this ratio in all the changes of temperature between the point of boiling water, (I may even say of freezing water,) and that of 280° of Fahrenheit's scale, and there does not appear to be any reason why the same law should not hold in higher temperatures.

"A doubt might possibly arise with respect to the existence of a sufficient quantity of water in gunpowder, to fill the space in which the powder is fired, with steam, at the moment of the explosion, but this doubt may easily be removed.

"The best gunpowder, such as was used in my experiments, is composed of 70 parts (in weight) of nitre, 18 parts of sulphur, and 16 parts of charcoal; hence 100 parts of this powder contain 67  $\frac{1}{10}$  parts of nitre, 17  $\frac{3}{10}$  parts of sulphur, and of charcoal 15  $\frac{1}{10}$  parts.

"Mr. Kirwan has shewn that in 100 parts of nitre there are seven parts of water of crystallization; consequently in 100 parts of gunpowder, as it contains 67  $\frac{1}{10}$  parts of nitre, there must be 4  $\frac{7}{10}$  parts of water.

"Now as one cubic inch of gunpowder, when the powder is well shaken together, weighs exactly as much as one cubic inch of water at the temperature of 55° F. namely 253,175 grains troy; a cubic inch of gunpowder in its driest state must contain at least 10  $\frac{9}{10}$  grains of water;

## EXPLOSION.

for it is 100 to 4,711, as 253,175 to 10,927. But besides the water of crystallization which exists in the nitre, there is always a considerable quantity of water in gunpowder, in that state in which it makes bodies damp or moist. Charcoal exposed to the air has been found to absorb nearly  $\frac{1}{3}$ th of its weight of water, and by experiments I have made on gunpowder, by ascertaining its loss of weight on being much dried, and its acquiring this lost weight again on being exposed to the air, I have reason to think that the power of the charcoal, which enters into the composition of gunpowder, to absorb water, remains unimpaired, and that it actually retains as much water in that state as it would retain were it not mixed with the nitre and the sulphur.

“As there are  $15\frac{4}{5}$  parts of charcoal in 100 parts of gunpowder, in one cubic inch of gunpowder, (= 253,175 grains troy,) there must be 38,989 grains of charcoal; and if we suppose  $\frac{1}{3}$ th of the apparent weight of this charcoal to be water, this will give 4,873 grains in weight for the water, which exists in the form of moisture in one cubic inch of gunpowder.

“If now we compute the quantity of water which would be sufficient, when reduced to steam under the mean pressure of the atmosphere, to fill a space equal in capacity to one cubic inch, we shall find that either that contained in the nitre which enters into the composition of one cubic inch of gunpowder, as water of crystallization, or even that small quantity which exists in the powder in the state of moisture, will be much more than sufficient for that purpose.

“Though the density of steam has not been determined with that degree of precision that could be wished, yet it is quite certain that it cannot be less than 2000 times rarer than water, when both are at the temperature of  $212^{\circ}$ . Some have supposed it to be more than 10,000 times rarer than water, and experiments have been made which seem to render this opinion not improbable; but we will take its density at the highest possible estimation, and suppose it to be only 2000 times rarer than water. As one cubic inch of water weighs 253,175 grains, the water contained in one cubic inch of steam at the temperature of  $212^{\circ}$  will be  $\frac{1}{2000}$ th part of 253,175 grains, or 0.12659 of a grain.

“But we have seen that one cubic inch of gunpowder contains 10,927 grains of water of crystallization, and 4,873 grains in a state of moisture; consequently the quantity of water of crystallization in gunpowder is 86 times greater, and the quantity which exists in it in a state of moisture, is 38 times greater than that which would be required to form a quantity of steam sufficient to fill completely the space occupied by the powder.

“Hence we may venture to conclude, that the quantity of water actually existing in gunpowder is much more than sufficient to generate all the steam that would be necessary to account for the force displayed in the combustion of gunpowder, (supposing that force to depend solely on the action of steam,) even though no water should be generated in the combustion of gunpowder. It is even very probable that there is more of it than is wanted, and that the force of gunpowder would be still greater, could the quantity of water it contains be diminished.

“From this computation it would appear that the difficulty is not to account for the force actually exerted by fired gunpowder, but to explain the reason why it does not exert a much greater force.”

Besides the common gunpowder, there are several other chemical compositions which are capable of exploding

with greater or less violence; and the most remarkable of these compositions are, the gunpowder formed with the superoxygenated muriate of soda, instead of nitre; that preparation of gold which, from its remarkable property, is called fulminating gold; the fulminating silver, Howard's mercurial powder, the common fulminating powder, which consists of nitre, potash, and sulphur, &c. The explosions of almost every one of these chemical compositions is louder than the explosion of an equal quantity of the common gunpowder; yet when confined in a barrel or other fit instrument, few of these compositions exert a force, or produce an effect equal to that of gunpowder. This, which at first sight may appear to be an inexplicable paradox, will be easily understood by considering, that the smartness of the report depends in great measure on the quickness of the inflammation or explosion; whereas the force of the explosion is mostly proportional to the quantity of elastic fluid, be it gas or vapour, which is generated, and that the abovementioned chemical mixtures explode quicker than common gunpowder, may be easily proved. Let, for instance, two trains of equal length be formed upon a stone pavement; viz. one with the common gunpowder, and another with Howard's mercurial powder, and let one extremity of each train come into mutual contact; so that by applying a red-hot iron to that point, both trains may be fired at the same time. It will be found that the train of mercurial powder goes off visibly much quicker than that of gunpowder; for when the former is entirely consumed, the fire of the latter will hardly have proceeded half way of the whole train.

The explosion of the gunpowder made with the superoxygenated muriate of soda, and Howard's mercurial powder, exert an immense force when fired in barrels or other like vessels. Fulminating gold and fulminating silver explode very readily, especially the latter, which, when once prepared, can no longer be touched; for it will explode, not only when heated a few degrees above the temperature of the atmosphere, but even when touched with any solid body. Yet when either of these preparations is confined in a barrel or other like instrument, and is inflamed, the force which it exerts is by no means equal to that which one who has heard the noise of their explosions would be led to expect. It is worthy of remark, that, upon the whole, no other composition hitherto discovered has been found preferable to the common gunpowder, for muskets, cannons, and other instruments of the like nature. Most of these preparations are considerably more expensive than the common gunpowder; some of them are not nearly so manageable as the gunpowder, for they will explode by the least touch or grinding, even by the friction of the stopple into the neck of the vessel that contains them; but the principal fault is that very property by which they might be expected to have a superior power; namely, the quickness of their explosion.

There is a certain time requisite for the motion of the wadding and bullet from the lower part to the muzzle of a gun, and the gradual inflammation of the gunpowder, when used in proportionate quantity, seems to correspond with that gradual movement of the bullet, wadding, &c. When the exploding composition goes off much quicker than the common gunpowder, that force which is exerted spherically all round, and quicker than the time during which the wadding; &c. can get along the cavity of the barrel, frequently breaks the barrel, and endangers the bystanders. We cannot illustrate this effect better than by mentioning the common and well-known observation, that though an open door may be shut by a gentle application of a child's

a child's hand, yet if you point a gun, and fire a bullet at it, the latter will make a hole through it without shutting, or closing it in the least.

Speaking of the force of explosions, it may naturally be required that we should treat of the force and effects of electrical explosions. But as the nature of such explosions cannot be properly understood without other particulars relative to the subject of electricity, their force and effects will be found described under the articles which belong to that extensive subject; such as *ELECTRIC Sparks*, *LEYDEN PHIAL*, *FIRE Balls*, *LIGHTNING*, &c.

It is in a manner similar to the effects of gunpowder, that water projected upon red-hot or fused metal, occasions a most powerful, and most dangerous explosion. In both cases the water is instantly reduced into steam, at a high temperature, consequently of very high elasticity; hence the force which is exerted is often prodigiously great; and there are instances recorded of whole founderies having been instantly demolished, in consequence of some persons having inadvertently spit upon the liquid metal. If a small quantity of water be poured upon red-hot charcoal, or red-hot glass, a hissing noise is heard; the part which is touched by the water loses its redness, and nothing else remarkable takes place, because the above-mentioned substances are bad conductors of heat, and it is only that part which is touched by the water that communicates its heat to the water, and this is not sufficient to convert the water suddenly into steam of very great elasticity. But metallic bodies are the best conductors of heat, and fused copper is particularly so; hence, when a small quantity of water happens to fall upon a large quantity of that metal, in a state of fusion, the heat from a great part of the metal rushes to the spot where the water is fallen, and instantly converts it into steam of high elasticity.

The explosion of a mixture of hydrogen and oxygen gases, or of hydrogen gas and common air, does likewise exert a considerable force, but not to be compared with that of gunpowder. These gases, when inflamed, expand considerably, but instantly after, they contract into an exceedingly narrow compass, which occasions the report; for, by the combustion, they are converted principally into water, the bulk of which is less than the ten or twenty thousandth part of the original bulk of the gases.

The last kind of explosion we shall take notice of, is produced not by the generation or contraction of an elastic fluid, but by a sort of mechanical derangement. Those lumps of glass with a long tail, or prolongation, which are well known by the name of *Glass Tears*, or *Prince Rupert's Drops*, are an instance of this kind. If one of these drops be held in the hand, and part of the tail is broke, a smart kind of explosion is heard, and the whole is instantly converted into powder. In order to understand the cause of this phenomenon, it is in the first place necessary to consider how these drops are formed. For this purpose the glass manufacturers take a quantity of the fused glass, (about half an ounce of it, and green bottle glass is the fittest for it,) and drop it in that state of incandescence into cold water; the consequence of which is, that the external part of the lump of glass is cooled and rendered solid long before the internal part of it. Then when the internal part is cooled, and of course contracts its dimensions, the external part being already cooled and settled, cannot follow it, so that it remains in a state of suspension somewhat like an arch; hence, when part of the lump is broken, the key-stone, as it were, of the arch, is removed, and the whole assemblage of particles is de-

VOL. XIII.

ranged. See *GLASS Tears*, for a more detailed explanation of these their properties.

Several other substances explode and are broken upon analogous principles. Such are glass vessels made for different purposes, and especially for electrical machines; also large cast-metal vessels sometimes spontaneously explode and break in the act of cooling. Sir William Hamilton mentions certain volcanic bodies, which he calls *volcanic bombs*, that explode probably on the same principle. They were large pieces of lava, which burst in pieces like bombs as they fell to the ground. These were observed in the great eruption of mount Vesuvius, which took place in the year 1779. The cause of volcanic explosions, as well as of those which accompany or precede earthquakes, is mostly attributed to the action of steam; but these kinds of explosions will be found particularly examined under the articles *EARTHQUAKE* and *VOLCANO*.

The use to which certain explosions are applied is so well known as not to require any particular description. Every body knows the various uses of shooting with gunpowder, especially in military affairs. The blasting or breaking of rocks, by means of the explosion of gunpowder, is likewise well known. But these uses, together with all the particulars that relate to them, are often mentioned in various other articles of this Cyclopædia; such as *GUNNERY*, *MINING*, *SHOOTING*, &c.

**EXPOLITION**, in *Rhetoric*, a figure whereby we explain the same thing in different phrases and expressions, in order to shew it more fully.

Expolition was the favourite figure of Balzac.

**EXPONAS VENDITIONI**. See **VENDITIONI**.

**EXPONENT**, from *expono*, *I express*, in *Arithmetic*. Exponent of a power denotes the number which expresses the degree of the power, or which shews how often a given power is to be divided by its root before it be brought down to unity.

Thus, the exponent or index of a square number is 2; of a cube, 3; the square being a power of the second degree; the cube of a third, &c.

Exponents are commonly written above, and somewhat towards the right-hand of the number or quantity whose power they express. Thus,  $3^5$ ,  $a^5$ , signify the fifth power of 3, and of  $a$ . See **POWER**.

**EXPONENT** is also used in the same sense with index or logarithm.

Thus a series of numbers in arithmetical progression being placed under another series in geometrical progression, are called the exponents, indices, or logarithms thereof. *E. gr.* in the two progressions,

Geom. 1, 2, 4, 8, 16, 32, 64, 128, 256, 512

Arith. 0, 1, 2, 3, 4, 5, 6, 7, 8, 9

0 is the exponent, index, or logarithm of the first term 1; 5 that of the sixth, 32, &c.

Hence, unity is to the exponent of a power as the logarithm of the root to the logarithm of its power; consequently, the logarithm of the power is had by multiplying the logarithm of the root by its exponent; and the logarithm of the root is had by dividing the logarithm of the power by its exponent.

**EXPONENT of a ratio**, is the quotient arising upon dividing the antecedent by the consequent.

Thus, in the ratio 3 to 2 the exponent is  $1\frac{1}{2}$ , and the exponent of the ratio 2 to 3 is  $\frac{2}{3}$ . See **RATIO**.

Hence, 1. If the consequent be unity, the antecedent is the exponent of the ratio. Thus, *e. gr.* the exponent of

the ratio 4 to 1 is 4; and again, the exponent of a ratio is to unity as the antecedent to the consequent.

2. Since in a rational ratio the exponent of a ratio is had by dividing a rational number by another rational, the exponent of a rational ratio is a rational number.

**EXPONENTIAL CALCULUS**, *Calculus exponentialis*, is a method of differencing exponential quantities, and of summing up the differences of exponentials. See **CALCULUS**.

**EXPONENTIAL curve** is that which is defined by an exponential equation.

Exponential curves partake both of the nature of algebraic and transcendental ones; of the former, because they consist of a finite number of terms, though those terms themselves are indeterminate; and of the latter, because they cannot be algebraically constructed, or represented by an algebraic equation. Thus  $ay = x^3$  is the equation of an algebraic curve;  $y = a^x$  is the equation of an exponential curve: this equation  $y = a^x$  denotes that any ordinate  $y$  is to a constant ordinate assumed equal to 1, as a constant quantity  $a$  raised to a power whose exponent expresses the ratio of the absciss  $x$  to the line equal to 1 is to the line taken for unit or 1, raised to the same exponent. Let  $b$  represent the line = 1, and the equation

$$y = a^x \text{ (since } y : b :: a^{\frac{x}{b}} : b^{\frac{x}{b}} \text{), will become } \frac{y}{b} =$$

$$\frac{a^{\frac{x}{b}}}{b^{\frac{x}{b}}}$$

Note,  $y = a^x$  is the equation of the logarithmic

curve. See **LOGARITHMIC**. See also **CURVE**.

**EXPONENTIAL equation**, is that wherein there is an exponential quantity. See **EQUATION**, &c.

**EXPONENTIAL quantity**, is a power whose exponent is an indeterminate or variable quantity.

Exponential quantities are of several degrees and orders: when the exponent is a simple indeterminate quantity, it is called an exponential of the first or lowest degree.

When the exponent itself is an exponential of the first degree, then the quantity is an exponential of the second degree. Thus,  $z^y$  is an exponential of the first degree, because the

quantity  $y$  is a simple flowing quantity; but  $z^y$  is an exponential quantity of the second degree; because  $y^x$  is an

exponential of the first degree; so also,  $z^y$  is an exponential

of the third degree, the exponent  $y^x$  being one of the second; and universally, the exponential quantity of any degree has for its exponent, the exponential quantity of the degree next preceding it. See Bernouilli Oper. tom. i. p. 182, &c.

**EXPORTATION**, in *Commerces*, the act of sending commodities out of one country into another.

Exportation is a part of foreign commerce (see **COMMERCE**), distinguished by the appellation *active*, or *selling part*, in opposition to *importation*, which is called the *passive*, or *buying part*. It is observed, as a general maxim, that commerce, when active, must produce a flow of riches, the balance being received in money; whereas, if it be passive, treasures will be exhausted, as the balance of trade must continually be made good out of the remaining coin. Hence, plenty of money in any place implies, that the quantity of goods exported far exceeds that of goods imported; and wherever money is scarce, it may be concluded that greater

quantities of goods have been imported than exported. See **EXCHANGE**.

It has been a principal object of commercial policy in almost every country, to encourage exportation, with the exception of a few articles; that of manufactured goods has been promoted with a view of encouraging the internal industry of the country, and that of foreign produce, as a means of drawing wealth from other countries by the profits of the carrying trade. The excess of the value of goods exported beyond that of the imports has usually been considered as a criterion of the profits which a country derives from foreign trade; but this is a fallacious mode of determining this important point, because advantageous foreign trade might long exist, even if the imports constantly exceeded the value of the exports. The laws in force relating to exportation consist principally of prohibitory or restrictive regulations concerning bullion, corn, wool, machinery, and tools used in various branches of the manufactures, the exportation of which, it is thought, might diminish the necessary supply of provisions for the consumption of the country, or enable foreigners to rival valuable branches of its manufactures. The acts relative to the exportation of wool, prohibit the exportation, not only of the commodity itself, but also of live sheep, rams, or lambs, from Great Britain, Ireland, Jersey, Guernsey, Alderney, Sark, or Man, on penalty of the forfeiture thereof, and of the ships conveying them; also 3*l.* for every sheep, &c. and three months' solitary imprisonment of the offender; for a second offence, 5*l.* for every sheep, &c. and six months' imprisonment; except wether sheep for ships' use, put on board by licence of the port-officer of the customs. A limited quantity of wool, however, is allowed to be exported from the port of Southampton to Jersey, Guernsey, Alderney, and Sark.

The duties on exportation, payable in Great Britain and Ireland, were formerly the principal branch of the revenue derived from foreign trade; but they are now of small amount compared with the duties payable on goods brought into the country.

The official value of all exports from Great Britain, for three years ending the 5th of January 1809, was as follows:

	British produce and manufactures.	Foreign merchandize.
Year ending 5th Jan. 1807	£. 27,402,685	£. 9,124,499
- - - 1808	25,171,422	9,395,149
- - - 1809	26,692,288	7,863,207

The actual value of British produce and manufactures exported from Great Britain, agreeably to the prices current, and to the declarations of the exporters, was, in the year ending the 5th of January 1809, £. 40,881,871.

The official value of imports into Great Britain from Europe, Africa, and America, during the same periods, is as follows:

Year ending 5th January 1807	£. 25,089,136
- - - 1808	25,453,149
- - - 1809	23,784,516

The official value of imports into Great Britain from East India and China is as follows:

Year ending 5th January 1807	£. 3,746,771
- - - 1808	3,401,509
- - - 1809	not ascertained.

The real value of Irish produce and manufactures exported from Ireland in the year ending the 5th of January 1809, computed at the average prices current, was £. 12,577,517.

108. *11d.* See CUSTOMS, and DUTY. See also COMMERCE.

Dr. Smith, in his "Nature and Causes of the Wealth of Nations," states and explains the principles upon which the exportation trade is founded. When the produce of any particular branch of industry exceeds what the demand of the country requires, the surplus must be sent abroad, and exchanged for something for which there is a demand at home. Without such exportation, a part of the productive labour of the country must cease, and the value of its annual produce diminish. The land and labour of Great Britain produce generally more corn, woollens, and hard ware, besides some other manufactures, than the demand of the home market requires. The surplus part of them must, therefore, be sent abroad, and exchanged in the manner already mentioned. It is only by means of such exportation, that this surplus can acquire a value sufficient to compensate the labour and expence of producing it. The neighbourhood of the sea-coast, and the banks of all navigable rivers, are advantageous situations for industry, only because they facilitate the exportation and exchange of such surplus produce for something else, which is more in demand there.

When the foreign goods, which are thus purchased with the surplus produce of domestic industry, exceed the demand of the home market, the surplus part of them must be sent abroad again, and exchanged for something more in demand at home. When the capital stock of any country is increased to such a degree that it cannot be wholly employed in supplying the consumption, and supporting the productive labour of that particular country, the surplus part of it naturally disgorges into the carrying trade, and is employed in performing the same office to other countries. The carrying trade is the natural effect, and symptom of great national wealth; but it does not seem, says Dr. Smith, to be the natural cause of it. Holland had formerly the greatest share of the carrying trade of Europe, and in proportion to the extent of its land, and the number of its inhabitants, it was the richest country in Europe. England, now the richest country of Europe, has appropriated to itself the greatest share of this trade. This ingenious writer suggests, that, whether the capital, which carries this surplus produce abroad, be a foreign or a domestic one, is of very little importance. If the society has not acquired sufficient capital both to cultivate all its lands, and to manufacture in the completest manner the whole of its rude produce, there is even a considerable advantage derived from the exporting of that rude produce by a foreign capital, in order that the whole stock of the society may be employed to more useful purposes.

Dr. Smith farther observes, in reference to this subject, that with a view of multiplying gold and silver, in which, it has been commonly supposed, the wealth of a country consists, it necessarily became the great object of political economy to diminish, as much as possible, the importation of foreign goods for home consumption, and to increase, as much as possible, the exportation of the produce of domestic industry: and, therefore, its two great engines for enriching the country have been restraints upon importation, and encouragement to exportation. The former were of two kinds, *viz.* restraints upon the importation of such foreign goods for home consumption as could be produced at home, from whatever country they were imported; and restraints upon the importations of goods of almost all kinds, from those particular countries, with which the balance of trade was supposed to be disadvantageous. These different restraints consisted sometimes in high duties, and sometimes in absolute prohibitions. Exportation was encouraged sometimes by drawbacks, sometimes by bounties, sometimes by advantageous

treaties of commerce, and sometimes by the establishment of colonies in distant countries. Thus it has been intended to increase the quantity of gold and silver in any country by turning the balance of trade in its favour. Our author has particularly examined what are likely to be the effects of these restraints and encouragements upon the annual produce of the industry of a country. According as they tend either to increase or diminish the value of this annual produce, they must evidently tend either to increase or diminish the real wealth and revenue of the country. See EXCHANGE, MONOPOLY, and *Balance of Trade*. Of the encouragements to exportation above enumerated, those which are called *Drawbacks* (see the article) seem to Dr. Smith to be the most reasonable. Concerning the grant of bounties; see BOUNTY.

EXPOSING, the act of setting a thing to public view.

In the Romish church, the sacrament is said to be exposed when it is shewn in public, uncovered, on festival days, and during the time of plenary indulgences.

EXPOSING is also used with a farther latitude; thus, we say it is prohibited to expose false and clipped money.

Such a house stands very high, and has a delicious prospect; but it is exposed to all the four winds. Such a city being on the frontiers, and not fortified, is exposed to the insults of every party of forces.

EXPOSING of *Children*, a barbarous custom practised by most of the ancients excepting the Thebans, who had an express law to the contrary, whereby it was made capital to expose children, ordaining at the same time that such as were not in a condition to educate them, should bring them to the magistrates, in order to be brought up at the public expence. (*Ælian Hist. Var. l. ii. c. 7.*) Among the other Greeks, when a child was born, it was laid on the ground; and if the father designed to educate his child, he immediately took it up; but if he forebore to do this, the child was carried away, and exposed. *Pitisc. Lex. Ant. in voc. Expositio.*

The Lacedæmonians, indeed, had a different custom; for with them all new-born children were brought before certain tryers, who were some of the gravest men in their own tribe, by whom the infants were carefully viewed; and if they were found lusty and well-favoured, they gave orders for their education, and allotted a certain proportion of land for their maintenance: but if weakly, or deformed, they ordered them to be cast into a deep cavern in the earth, near the mountain Taygetus, as thinking it neither for the good of the children themselves, nor for the public interest, that defective children should be brought up. Plutarch takes notice of this law of Lycurgus, and passes no censure upon it.

Many persons exposed their children only because they were not in a condition to educate them, having no intention that they should perish. It was the unhappy fate of daughters especially to be thus treated, as requiring more charges to educate and settle them in the world than sons.

The parents frequently tied jewels and rings to the children they exposed, or any other thing whereby they might afterwards discover them, if Providence took care of their safety. Another design, in adorning these infants, was either to encourage such as found them to nourish and educate them, if alive; or to give them human burial, if dead.

The places where it was usual to expose children were such as people frequented most. This was done in order that they might be found, and taken up by compassionate persons who were in circumstances to be at the expence of their education. With this intention the Egyptians and

Romans chose the banks of rivers, and the Greeks the highways.

Dionysius Halicarn. (Antiq. Rom. l. ii.) informs us, that Romulus obliged the citizens to bring up all their male children, and the eldest of the females. They were allowed therefore to destroy all their female children but the eldest. And even with regard to their male children, if they were deformed or monstrous, he permitted the parents to expose them, after having shewn them to five of their nearest neighbours. In Cicero's third book of laws, (cap. 8.) there is a passage, from which it has been concluded, that the law of Romulus, with regard to the exposing and destroying of male children that were remarkably deformed, was confirmed by a constitution of the twelve tables. It appears, from a passage in Terence, that this inhuman custom of exposing and destroying children, especially females, was not uncommon even among parents of the best character. Sentiments of this kind were published with applause on the Roman theatre: and we learn from Seneca (de Ira, l. i. c. 15.) that so late as in his time, it was usual among the Romans to destroy weak and deformed children. "Portentosos fetus extinguimus: liberos quoque, si debiles monstrisque editi sunt, mergimus."

This unnatural practice was prescribed and approved even by the more eminent philosophers. Plato (Republ. l. v.) recommends it to be ordered by law that men or women, who are past the age of having strong children, should take care that their offspring, if they should have any, should not come to the birth, or see the light; or if that should happen, that they should expose them without nourishment. Aristotle (Politic. l. vii. c. 16.) expressly says, that it should be a law not to bring up or nourish any child that is weak or maimed; and that when the law of the country forbids to expose infants, it is necessary to limit the number of those who should be begotten; and if any one begets children above the number limited by the laws, he advises to procure abortion before the fetus has life and sense. The practice that has long prevailed among the Chinese, and that subsists among them even to this day, is well known.

**EXPOSITION**, the act of exposing. See **EXPOSING**.

**EXPOSITION** is likewise applied to the interpretation or explication of an author, or passage therein. See **EXEGETIS**.

**EXPOSITION of deeds**, in *Law*, shall be favourable, according to the apparent intent; and be reasonable, and equal, &c. Co. Litt. 313.

**EXPOSITION, expeditio**, in *Rhetoric*, is sometimes used for division. See **DIVISION**; and see also **EXERGASIA**.

**EXPOSITION**, in *Gardening*. See **EXPOSURE**.

**EXPOSITOR**, or **EXPOSITORY**, a title which some writers have given to a lesser kind of dictionaries or vocabularies, serving to expound or explain the meaning of the obscure or difficult words of a language.

It is also used in the same sense with commentary and paraphrase.

**EX POST FACTO**, in *Law*, denotes something done after another thing that was committed before. An estate granted may be made good by matter ex post facto, that was not so at first, by election, &c.

**EXPOSTULATION, EXPOSTULATIO**, in *Rhetoric*, a complaint addressed to a person from whom we have received some injury. It varies according to circumstances.

**EXPOSURE**, or **EXPOSITION**, in *Gardening*, the aspect or situation of a garden wall, building, or the like, with respect to the sun, wind, &c.

There are four regular kinds of exposures, *viz.* east, west, north, and south; but it must be observed that among gardeners these terms signify just the contrary to what they do among geographers.

The gardeners, in effect, do not give the names east, west, &c. to the places where the sun is, but to those whereon he shines; and they consider the manner wherein he shines, whether as to the whole garden, or some of its sides.

If they find, that the sun at his rising, and during the first half of the day, continues to shine on one side of a garden or wall, they call that an eastern exposure, or east wall, &c. and if the sun begin to shine later, or end sooner, it is not a proper eastern exposure.

For the same reason, they call the west the side the sun shines on the latter half of the day; *i. e.* from noon to night; and accordingly, the south, or southern exposure, is the place whereon he shines from about nine o'clock in the morning till night; or which, in the general, he shines longest on in the whole day; and the part he shines least on is the north, or southern exposure, at what hour soever it begin or end, being usually from eleven o'clock to one.

The eastern and southern exposures are, by common consent of all gardeners, the two principal, and have a considerable advantage above the rest. A west exposure is not much amiss; at least, it is better than a northern one, which is the worst of all: each has its inconveniences.

The eastern, commencing differently at different seasons of the year, and ending about noon, subjects the trees, &c. to the N.E. winds, which wither the leaves and new shoots, blow down the fruit, &c. beside that it has little benefit of rains, which come mostly from the west. Yet does the reverend Mr. Laurence judge the east better than the west-wall for all kinds of fruit; not that it has more hours of sun, or that there are any peculiar virtues in the eastern rays, but because the early rays of the sun do sooner take off the cold chilly dews of the night.

M. Gentil recommends the eastern exposure as best for all kinds of peaches; adding, that they ripen soonest, grow bigger, are better coloured, and of a finer taste, than in any other; but Mr. Carpenter restrains the rule to the early and middle sorts; for the backward, he rather chooses a southern, or south-east exposure, which is best for all late fruits, because the influence of the sun is strongest, and continues longest.

The western, accounted from half an hour past eleven till sun-set, is backwarder than an eastern one by eight or ten days; but it has this advantage, that it receives little damage from the frosts, which melt before the sun comes to shine upon the fruit, and fall off like dew, without doing any prejudice; so that it may bear apricots, peaches, pears, and plums; but it is incommoded with north west winds in the spring, as also with the autumnal winds, which blow down a great quantity of fruit.

According to Mr. Miller, the best aspect or exposure for walls in England is the point to the eastward of the south; because those will enjoy the benefit of the morning sun, and be less exposed to the west and south-west winds, which are very injurious to fruits in England, than those walls which are erected due south; the next best exposure is due south, and the next to that south-east, which is preferable to the south-west. Other walls, however, may be planted with fruit-trees that suit their several exposures.

The northern exposure is the least favourable of any in England, as having very little benefit from the sun even in the height of summer, therefore can be but of little use, whatever may have been advanced to the contrary. For although many sorts of fruit-trees will thrive and produce

fruit in such positions, yet such fruit can be of little worth, since they are deprived of the kindly warmth of the sun to correct their crude juices, and render them well tasted and wholesome. It is therefore to little purpose to plant fruit-trees against such walls, except it be for fruit intended for baking, &c. in which case the fire will ripen and render those juices wholesome which could not be performed while growing.

In such situations, morelli cherries for preserving may be planted, and white and red currants to come late, after those which were more exposed to the sun are gone; and if the soil be warm and dry, some sorts of summer pears will do tolerably well on such an exposure, and will continue longer in eating than if they were exposed to the sun. But winter pears should by no means be planted in such an aspect, as has been practised by many ignorant persons, if we find that the best south walls in some bad years are barely warm enough to ripen them. Duke cherries planted against walls exposed to the north will ripen much later in the season; and if the soil be warm, will be well flavoured, and continue a month later than others. Miller.

The southern exposure, accounted from about nine till four, is recommended for peaches, pears, grapes, and plums.

EXPRESS, something that is precise in formal terms, or for some particular design. I told him as much in express terms; he gave me a commission express; he had express orders; a courier was dispatched express.

We also say, somewhat abusively, to send an express, meaning a courier.

EXPRESS *Condition, Contract, Malice, and Warranty.* See the substantives.

EXPRESSED OILS, are such as are procured from bodies only by pressing; as the oils of olives, almonds, and the like. See OIL.

EXPRESSED *species.* See SPECIES.

EXPRESSION, in *Algebra*, denotes the value of a quantity expressed or represented under an algebraic form: thus, if  $x = \sqrt{a^2 + b^2}$ , and  $a$  and  $b$  are known, the value of  $x$  is known. See EQUATION.

EXPRESSION, in *Chemistry, Pharmacy, &c.* the act of expressing out, or extracting the juices of oils or plants, fruits, or other matters, by squeezing, wringing, or pressing them in a press. This is one of the three modes of obtaining them; the other two being *infusion* and *decodion*, which see. The hard fruits should be well bruised, and herbs moderately bruised, before expression. They are then to be inclosed in a hair or other bag, and pressed between wooden plates in the common screw press, till the juice ceases to run. The expression of oils is performed nearly in the same manner as that of juices, by means of iron plates, or the apparatus of an oil-mill, adapted to this purpose. The insipid oils of all unctuous seeds are obtained uninjured by this operation, if performed without the aid of heat, which, though it may promote the extraction of the oil, gives it an ungrateful flavour. The oils expressed from aromatic substances generally carry with them a portion of their essential oil.

EXPRESSION, in *Music*, is a quality by which a musician manifests his feeling, and executes with energy all the ideas with which he ought to impress the hearer, and all the sentiments which the composer intended to express. There is an expression in composition as well as in its execution, and it is by their concurrence that the most pleasing and agreeable effect results.

To give an expression to his works, a composer ought to seize and compare all the relations which can be found between the features of his object, and the productions of his

art; in a musical drama, he ought to know and feel the peculiar cast of all the characters, in order severally to exhibit them exactly as delineated by the poet; for as a good painter does not throw the same light on every figure, neither will the able musician give the same energy to all the sentiments, nor the same force to every figure, but will put each part in its true place, less to give it weight, individually, than to contribute to the effect of the whole.

After having well considered what a character has to say, he meditates how he shall say it; and here begins the application of the precepts of his art, which is to find the particular language in which the actor would wish to make himself understood.

Melody, harmony, movement, choice of instruments and voices, are the elements of the musical language; and melody, by its immediate connection with the grammatical and oratorical accent, is that which gives a character to all the rest. So that it is constantly from melody that the principal expression should be derived, as well in instrumental as vocal music.

What a composer therefore has to express by melody is tone of voice, with which the sentiments can best be rendered; and care should be taken not to mimic that of theatrical declamation, which is in itself only an imitation, but the voice of nature speaking without affectation and without art.

The composer will therefore at first seek a kind of melody which shall furnish musical inflections the most consonant to the sense of the words, always lowering their expression to the thought, and the thought to the interlocutor's state of mind; for when we are strongly affected, all that we say in a manner favours of the general sentiments which govern us; and we never chide what we love in the same tones as we should an indifferent person. Our speech is differently accented according to the different passions by which we are agitated; sometimes acute and vehement, sometimes languid and monotonous, sometimes varied and imperious, sometimes smooth and tranquil in its inflections. Thence the musician regulates the choice of keys which he uses in his melody, and the different places in which he employs voice, keeping it down with small intervals to express the languor of sorrow and dejection; and straining it with acute sounds in passion and grief; driving it rapidly through all the intervals of the diapason in the agitation of despair, or the turbulence of distracted passions. Above all it must be remembered, that the charms of music consist not only in imitation, but in an agreeable imitation; and that the declamation (or recitative) itself to have its full effect, should be subordinate to melody; so that there is no painting sentiment without giving it this secret charm inseparable from it, nor touch the heart without pleasing the ear. And this is still very conformable to nature, which gives to the tone of voice of persons of sensibility, certain touching and delicious inflections, which those who feel nothing never possessed. Never, therefore, mistake rough and coarse for expressive, nor harshness for energy. Give not a hideous picture of the passion which you wish to paint, nor imitate the performers at the French opera, where the voice of passion resembles a complaint of the colic, more than transports of love.

The natural pleasure which results from harmony, augments in its turn the moral pleasure of imitation, in uniting the agreeable sensations of chords to the expression of the melody, upon the same principle as that just mentioned. But harmony does still more; it enforces even the expression in giving more truth and precision to melodious intervals; it animates their character, and exactly marks their place in the order of the modulation; it calls back the preceding, announces

## EXPRESSION.

announces that which ought to follow, and thus connects the phrases in the melody, as ideas are linked together by grammar in a discourse. - Harmony, regarded in this light, furnishes the composer with powerful means of expression, which escape him when he seeks expression in harmony alone; for then, instead of animating the accent, he extinguishes it by his chords, and all the intervals, confounded in a continued crowd of combined sounds, offer to the ear only a series of fundamental chords, which have nothing touching or agreeable in their effect, and often not only suffocate the melody, but the sense of the words. - What then must the harmonist do to fortify the expression of the melody, and give it more effect? He will carefully avoid covering the principal sound in the combination of chords; he will render all the notes of the accompaniment subordinate to the vocal part; he will give relief and energy to it by the concurrence of other parts; he will enforce the effect of certain passages, by the chord of the sharp 7th; he will disguise others by supposition or suspension, in making no provision for them in the base; he will gain strong expressions by major discords, he will reserve the minor, for tender sentiments; sometimes he will unite all his parts by smooth and flowing notes; sometimes he will contrast them with the melody by pointed notes; sometimes he will fill the ear with full harmony, and sometimes enforce the accent by the choice of a single interval. He will render present and sensible the chain of modulation throughout, and will make the base and its harmony serve to determine the place of each passage in the key, in order that no interval or trait of melody shall be heard, without feeling at the same time its relation with the whole.

With respect to rhythm, formerly so powerful as to give force, variety, and ornament to poetical harmony; if modern languages less accentuated and less prosodic have lost this charm, our music can substitute another more independent of speech in the precision of measure, and in the combination of its proportions, whether moving together or separately in each part.

Quantity in language is almost wholly lost in notes of music; and the music, instead of speaking with words, borrows, in some sort, from the measure a language apart.

The force of the expression consists in this particular, in the uniting these two languages as much as possible together, in such sort, that if the measure and the rhythm speak not in the same manner, they will at least say the same things.

Chearfulness, which gives vivacity to all our movements, ought to do the same in musical measures. Melancholy locks up the heart, relaxes all our motions, and the same languor is felt in the melodies which it dictates; but when grief is poignant, or great conflicts are passing in the mind, speech is unequal; it moves alternately with the slowness of the spondee and the rapidity of the Pyrrhic, and sometimes suddenly stops short, as in accompanied recitative; it is on this account, that the most expressive music, or at least the most passionate, is commonly that in which the times or portions of each bar, though equal in themselves, are the most unequally divided; whereas the image of sleep, of repose, of peace of mind, require small exertion of voice, and are naturally painted with notes of equal length, which move neither quick nor slow.

There is one observation which the composer ought not to neglect, and which is, that the more studied and extraneous is the harmony, the slower should be the movement, in order that the mind may have leisure to disentangle the discords, and follow the rapid chain of modulation. Nothing but the last degree of fury can permit the union of rapid measures and harsh chords. When the head is

distracted, and the actor, by violent agitation, seems not to know what he says, this energetic and terrible confusion may be communicated to the mind of the spectator, and, in like manner, make him lose his reason. But if the composer is not inflamed and sublime, he will only be coarse and cold; if he does not throw the audience into a delirium, he runs a great risk of a failure: for he who loses his reason is only mad in the eyes of those who preserve it, and insanity is no longer interesting.

Though the greatest force of expression is derived from the combination of sounds, the quality of their tone is not indifferent in the effect. There are voices so strong and sonorous as to impose by their force; others thin, flexible, and fit for execution; others again so touching and delicate as to penetrate the heart by soothing and pathetic strains. In general, treble voices and acute are fittest to express tenderness and affection; bases and baritones for intemperate passion and choler; but the Italians have banished bases from their serious operas, as a part, of which the melody is too rude and boisterous for the heroic style, and have substituted in their stead tenors, of which the melody has the same character, with a more agreeable effect. They employ base voices in the grotesque and ridiculous parts of their comic operas with more propriety.

Instruments have also their peculiar expressions, proportioned to their quality of tone, force, and compass. The flute is tender, the hautbois cheerful, the trumpet military, the horn sonorous, majestic, and proper for grand expressions. But there is no instrument of more varied expression, and more universally useful, than the violin. This admirable instrument is the foundation of every orchestra, and can furnish a great composer with all the effects which mean musicians vainly seek in a multitude of different instruments. The composer ought to be acquainted with the finger-board of the violin, to consider the shifts, and know how to write arpeggios, by distinguishing the open from the stopped strings, and to choose and make use of keys according to the different characters they have upon that instrument.

It is in vain for the composer to attempt to animate his orchestra, if the ardour which ought to reign in it does not inflame the performers. The singer who only sees notes in his part, is not qualified to seize the expression of the composer, nor to give one of his own to what he sings, if he has not well comprehended the sense. He must understand what he reads before he can make it comprehended by others; and it is not enough to be possessed of general sensibility, if not particularly energetic in the language we speak. Let him begin therefore by thoroughly understanding the character of the melody which he has to execute, its expression of the words, the distinction of its phrases, the accent which it has in itself, that which it requires in the voice of the singer, the energy which the composer has given to the poet, and that which in his turn he can give to the composer. Let him resign his whole powers, then, to all the enthusiasm which these considerations shall have inspired; he should express every thing as completely as if he were at once the poet, composer, actor, and singer, and he will then have all the animation which it is possible for him to give to the work which he has to execute.

In this manner he will naturally embellish with taste and delicacy airs that are only elegant and graceful; with spirit and fire, such as are animated and gay; with sighs, the tender and pathetic; and with all the agitation of forte and piano, such as are expressive of rage and fury. Whenever the musical and oratorical accents are united (as in arie parlanti), wherever the time shall be strongly marked, and serve as a guide to the accents of the melody; wherever the accompaniment

## EXPRESSION.

companionment and the voice shall so agree in their effects as to form only one melody, and the hearer, deceived, wholly attributes to the voice the passages which the orchestra embellishes; and, finally, wherever lober ornaments, judiciously applied, manifest the abilities and facility of the singer, without disguising and injuring the melody, the expression will be sweet, agreeable, and animated; the ear will be delighted, and the heart affected; nature and art will at once concur in pleasing the hearer, and there will reign such a coincidence between the words and the music, that the whole will seem to proceed from one delicious language, which can say every thing, and always please.

This is more a dissertation than an article of a dictionary, but these are the sentiments of the citizen of Geneva, to most of which in music we readily subscribe, as he is ever more reasonable and consistent in speaking of that art than on any other subject. His views concerning dramatic music are always so ingenious, elevated, and refined, that we cannot resist translating him. Though we fear that the French, with all their present rage for Italian music and Italian expression, will not adopt them; and the Italians themselves, in their most happy moments of conception, have been successful from instinct and enthusiasm, more than precepts or reflection.

EXPRESSION, in *Oratory*, denotes the manner of delivering or conveying one man's ideas to another. Accordingly it denotes that felicity of discriminative energy in the reader, speaker, or reciter, by which the characteristic beauties or peculiarities, whether of language, sentiment, or passion, in a composition or oration, are forcibly and happily illustrated; and the various shades and transitions of style, signification, feeling, and allusion, in such composition or oration, are distinctly and interestingly marked. Expression in this, as in every other art, is one of the chief constituents of excellence; and contradistinguishes the elocutionist of taste and genius, from the mere mechanical reader or declaimer. It depends chiefly upon that quickness and vitality of perception which may be regarded, in some degree, as an original gift of nature, and on that prompt and perfect sympathy between the perceptive faculty and the executive organs, which it is the highest glory of art and practical exercise to produce.

EXPRESSION is more particularly used for the elocution, diction, and choice of words in a discourse. See ELOCUTION.

It is not enough that a poet or orator have fine thoughts, he must likewise have a happy expression. Defects in the expression ordinarily arise from defects in the imagination: abundance of the beauties of the ancient writers are annexed either to expressions which are peculiar to their language, or to relations, which, not being so familiar to us as to them, do not give us the same pleasure.

EXPRESSION, *diversifying of*, in *Rhetoric*. See DIVERSIFYING.

EXPRESSION, in *Painting*, principally consists in the representation of those attitudes of the body, and variations of the countenance of men, which always accompany and denote the immediate influence of the passions of their minds. Besides this more important use of the word, it is used in painting to signify the representation of any object by a mode of execution agreeable to its nature, its character, and the situation it holds in the work. When wrought with just sense and propriety in these respects, it is said to be *well expressed*. We will first consider it in the former and more useful sense.

The passions which influence the conduct of men have each a general character of expression, by look or gesture,

attached to them in the whole race of mankind; and they are also marked in individuals by peculiarities, arising from the temperament and constitutional habits with which each of them is endowed by nature.

To seize and represent with energy these characteristics of the passions of the mind, and accompany their representation without diminishing its force, with the varieties appropriate to the individual personages introduced into a picture, is the essence, the soul of art. The slightest sketch possessing this quality, acquires an interest unimpaired by, and far above, that excited by the most highly and excellently wrought pictures which are void of it.

Very few painters, amongst the immense numbers of those who lay claim to the name, have been happy enough to obtain a super-eminent degree of expression in their works; indeed it is a task of extreme difficulty to overcome, requiring the soundest sense to select the knowledge of it, and the greatest ability in art to represent it when understood. The man who aims at it, besides being an ever active observer, should possess great susceptibility of mind to enter into the feelings of others, and thus draw, as it were, from himself: yet that susceptibility should be under the regulation of sound discernment, and cool dispassionate judgment, to enable him to discriminate the fictitious representations of passion, from those natural unartificial actions, and looks, dictated by, and arising from, genuine feeling; and in his continued observations upon the actions and aspects of men under their influence, he should be careful to separate those points which identify a peculiar passion, and distinguish it from others that are nearly allied to it.

Artists endowed with very considerable talents have failed in two different ways in their endeavours to embellish their works with this valuable quality. Some, by an over-anxious desire to give strength and energy to their expressions, have carried them into artifice and bombast: others, on the contrary, wishing to unite the beautiful with the pathetic, have only rendered their works insipid and uninteresting in expression; and it appears that he who is obliged to labour to produce it, who does not work from a clear comprehension of the characteristic lines of an expression in its simplest and most undisguised shape, can never effect the representation of it to any degree of perfection, and the beholder of his works will still leave them unimpressed with any portion of the sensation the real passion is calculated to produce; the only true test of the value of works of art, as far as relates to expression.

“By tedious toil no passions are express’d,  
He who conceives them strongest paints them best.”

The power of rendering, or producing expression in painting, is, next to grace and elegance, the least communicable talent of those requisite to form a perfect painter. He who attempts to obtain it, if not originally gifted by the great Author of nature with a peculiar propensity to observe and imbibe the leading features which constitute its excellencies, follows a phantom that will for ever elude his grasp. If, however, he happily possesses that inclination, he may obtain some assistance in his pursuit of it from the works of others, which will shorten his labour; but will not lead him to the ultimate point of his desire; to that, the study of nature can alone effectively induce.

We allude to some general rules given by artists who have communicated the result of observations made in their endeavours to obtain an understanding of the expression of the passions of the mind, in the countenances and actions of men; and they are by some, whose names authorize reliance upon their observations, particularly Lionardo da Vinci,

Trattata

## EXPRESSION.

Trattata de la Pittura, and Le Brun's Passions. They have pointed out and illustrated those actions of the countenance and figure which most strongly designate the reigning influence of particular passions.

These rules, however, go only a short way in a general view of the subject; much less do they comprize what is requisite, when the multitudinous varieties of expression in the almost infinitely varying countenances and habits of men of all degrees are taken into consideration. How, indeed, can it be possible to direct the means of obtaining with certainty that which is in itself so infinitely divisible, as the course of the feelings and dictates of the ungovernable heart of man, and his corresponding actions and turns of feature?

It is in having ascertained and established the features of the more strong and leading passions, that these general rules are found useful. We learn from them, that the influence of excessive joy or laughter draws all the features of the face upwards; that grief reverses that order, and draws them downwards. Violent anger distorts them, and enlarges their appearance, particularly the eyes and nostrils; and the action of the body is violent, with quick and short motions. Desire enforces an eager advancing action towards its object, and the eyes and mouth are somewhat expanded. Acute pain is generally expressed by a mouth somewhat opened and drawn back, the eyes raised, and partly covered by the upper eye-lid; and the eye-brows drawn closely together, wrinkling the forehead. Fear is denoted by expanded eyes and mouth, the eye fixed upon the exciting cause, the hair elevated and thickened, the colour livid, and the figure drawn back as if attempting to retire from the object which causes the alarm. The effects of the sensation of scorn or hatred on the figure and countenance are marked by the mouth being closed firmly, and the lips drawn down at the corners; whilst the elevation of the nostril causes the middle of the upper lip to rise; the forehead is strongly pressed, and the brow falls over the eyes, which express the passion best when they are turned sideways, towards the object, with the body inverted from it. Awe, or veneration, produces a general inclination of the body, and the head still more so, towards the object exciting it.

Under one or other of these passions and expressions all the feelings of our minds are more or less ranged; and of course will participate more or less of the indications of them, according to the excitation they meet with: therefore, so far the general rules will be of use in their representation. But mankind, from their various modes of education, their habits, and manners, accompany these sensations, when excited in them, by peculiarities which it is of the utmost importance to the painter justly to discriminate, and be careful not to give that action to one, which, in propriety, belongs to another; not to attach the vulgar action of an uncultivated clown, to the dignified character of a man of rank and liberal education.

Besides remarking the expressive characters of the stronger passions, great attention is requisite to be paid to the physiognomical expression of the countenance, and of the figure (if one may so speak); the influence of which is daily felt and acknowledged. Though our information upon that subject is much thwarted by the effect of education and reflection, yet its basis is just and firmly fixed, as every day's experience proves. Persons whose features and general forms correspond, are found to be correspondent also in character; that is, in their natural propensities: one of two, thus similarly formed, may have cultivated his mind more than the other, and education and society may have taught him to mask or disguise his inclinations; but nature is still true to herself, and the same general disposition re-

mains. Nay, it goes still further; young persons not naturally addicted to vice, being drawn by accident or early association to continue in the practice of indulgence, acquire, in process of time, a change of feature and expression, in great measure similar to that form usually indicative of the vice or passion indulged in, where it is implanted by nature.

In this, therefore, we have a ground of expression which is well worthy, indeed very necessary, to be carefully attended to by those who aim at perfection in the art of painting. They ought to make themselves acquainted with the forms that belong to the peculiar inclinations and different degrees of capacity of mind in the persons they chuse to bring forward in their works, of whatever class they may be. They should not put into the face of a man of mild character any of the features indicative of warm passions; in such an one the eye should not have an eager look; the nostrils should not be large, or inflated; all the lines should be smooth, and have little variation of form. And, on the contrary, when the figure of one whose disposition is naturally hot and impetuous is introduced, he should not have a smooth straight forehead; which is indicative of mildness and suavity; his nose should not be straight; nor his mouth gently undulating, of a mild pleasing character: though he may not be in the act of exerting his natural impetuosity of character, yet he should have the appearance of one who would be easily roused to that feeling and expression. A man of great sense and intellect should not be represented with the features that characterize imbecility; nor the weak, and undecided character, have the forms denoting sense and intellectual power; and it should be constantly remembered, that though every passion, every sentiment of the mind, has its peculiar expression; every particular person has his peculiar mode of expressing it.

In representations of the passions, 'tis not form alone which is required to perfect the work: though that indeed yields a very strong impression of it, yet its effect is greatly heightened when a proper tone of colour is superadded. By colour we judge of health or sickness, of youth and age, as well as by form: The fallow hue of melancholy is proverbial. It is well known how anger affects the hue of the countenance; in some it produces a violent flush of blood, and consequent redness of colour, even almost to blackness: in others a pallid hue denotes it, or a change from one to the other rapidly succeeding. The malignant passions are generally accompanied in their expressions by a pallid tone of colour: and the more noble sentiments by the reverse. A man performing a benevolent action feels a degree of satisfaction which affects his countenance; his eyes exhibit his sentiments by their liveliness, and his mouth by its gentle curves at the corners, whilst his cheeks bear (what is perfectly understood so as to be admitted a common phrase) the cheerful glow of humanity stamp on them. Clearness of complexion, and colour in the cheeks, indicate youth and health; fallowness, and the loss of the ruddy hue of colour, sickness and age. The inhabitants of the town, and of the country, exhibit the same distinctions; as also the studious man and the sportsman. Independent of the individual hue of the character represented, one general tone over the whole picture should prevail, correspondent to the subject. Thus, if it be one of a grave cast, the tone of colours should be low, yet rich; and though harmonious not monotonous. If, on the contrary, the subject is gay, the hues of the colouring should be bright and cheerful, and greatly diversified; and every part of the picture should assist in expressing the nature of the subject chosen for representation.

It is attention to this point which gives to painting its real value, its intrinsic worth; and separates it from the

more vulgar or merely mechanical arts. Hence it becomes of moral utility, and its power is not surpassed by the poetic, or other effusions of the pen, in the force and vivacity of the impressions it is calculated to produce. Of this there are many notices given to us in history. Alexander is said to have trembled and grown pale on seeing a picture of Palamedes betrayed to death by his friends: it bringing to mind the remembrance of his treachery to Artilonicus. It is also related of an Athenian courtesan, that in the midst of a riotous banquet, calling her eye on the portrait of a philosopher marked with the happy character of virtue and temperance; she was struck with so lively an image of her own unworthiness, that she instantly went home and became an example of temperance. In both these cases, to the truth of the expression must be ascribed the force with which the pictures wrought upon the observers; and produced the powerful impulse related.

It appears, indeed, to have been the principal object of attention with the ancient Greeks, and very naturally so; for in the beginning of an art, before any rules for regulating its efforts were adopted the artist's attention must of course have been solely directed to relating his story; and whatever assisted in effecting that, was pressed into the service. First of all, we are told, the efforts were so rude it was necessary to explain them: afterwards labels were placed as issuing from the mouths of figures; and other means of giving the ideas, supposed to occupy their minds, were adopted, till at last the artists arrived at the perfection of imitations of nature; and by giving their figures the actions and expressions appropriate to their situations, caused them to tell their own story, and impress all its interest on the beholders, without any extraneous aid. Unhappily, excepting the few pictures found at Herculaneum, and those are of a trivial kind, we have none of their works in this art to judge of the degree of perfection they arrived at in this most important point of it; but we have the testimony of many authors, some of whom speak as eye-witnesses, by whom we are led to believe, on convincing grounds, that their best pictures were full fraught with this best of good qualities; and there is no reason to doubt the truth of the report, when we see the sculpture of the same period which remains to us, so rich in possession of it.

In their statues, which were principally of gods, a great degree of minutiae of expression does not appear to have been the object of their attention, as far as relates to the passions, the representation of which they seem properly to have regarded as degrading to the dignity of a divinity. A calm untroubled state of mind appears in their countenances, and governs their looks and actions, but each has its appropriate character. What can be more dignified and majestic than the countenance of the Jupiter? Yet the line which its air, partaking somewhat of severity, inspires, is so blended with mildness, that it produces implicit confidence and veneration. The Apollo Belvedere has also the dignity of the godhead shining in it; but less imposing and overpowering, of a milder character, and the expression of his figure and action is perfect; no one doubts the intent of it for an instant; and this just discernment, and impress of character, run through the whole class of statues of the primary deities of the Greeks. The Venus, the Bacchus, the Hercules, &c. have each their distinctive line of character without passion, whose influence they are supposed to be exalted above, whilst in the lower orders, the fauns and nymphs, and rural deities, are no less properly marked with characteristic features and actions. In the figure of Laocoon destroyed with his sons by serpents, the authors (who were three) have exhibited a most powerful extent of feel-

ing and power in expression, remaining almost unrivalled in subsequent productions; the agony of pain and distress of mind are spread over the whole work which chills the beholder with horror.

Correspondent with this powerful effect is that related of and attributed to their pictures. Pliny says of Aristides, "that he infused into his pictures all the passions of the soul." It is said, "that Parrhasius, in his picture of Philoctetes, had renewed the pains of the hero, as seen in his parched deep sunk eyes, and the tears which flowed from them;" (Anthol. lib. 4.) and the epigrammatist concludes with a handsome compliment to the painter, blaming him "for not allowing the sufferings of Philoctetes to end with his life." Philostratus, Vita Apollonii. cap. 10. says, speaking of the Ajax of Timotheus, "we cannot do justice to the picture where Ajax is represented distracted, unless we previously form in our minds the image of his condition. The picture of "Medea contemplating the Murder of her Children," by the same painter, was the subject of numerous epigrams (Anthologia); so that it must have been very powerful to excite so much emulation among the wits to celebrate it. It was said to represent in her face, fury mixed with pity of the innocence of her children, who were represented smiling at the dagger in her hand. Ovid says, "her crime was confessed in her eyes." Plutarch says of Lyfippus the painter, that he was ingenious as well as sublime; that from the slight inclination of the neck natural to Alexander, he invented a sublime expression; making him look up to the heavens with manly boldness, and commanding majesty. The same author (in Timoleon) praises the paintings of Nicomachus "for their just expression," comparing them "to the poetry of Homer in grace and facility;" and Apelles in this point affirmed himself superior to other painters, though inferior in some others of less importance. It is needless to repeat the well known story of Timanthe's picture of the Sacrifice of Iphigenia, and of his artifice in hiding the face of the father, having exhausted the force of expression in the beholders; commendations and imitations of it are met with every where; and of his ingenious contrivance to convey an idea of the immense size of a Cyclops, by drawing some Satyrs measuring his figure with a thyrsus; and Pliny remarks of him on this occasion, that "in all his works there is more understood than is marked, and though his execution be matterly, yet his ideas exceed it."

Whatever allowance be made for the zeal and strength of terms with which persons at all times describe those things, than which they are unacquainted with any thing better, and which must have been the case in the early periods of art, the writers not being so learned in it as the painters who made it their continual study; yet we cannot refuse belief to a wonderful extent of power in rendering expression among the Greek painters, accompanied, as (it has been before observed) these descriptions of it are, by the actual effect in sculpture. It is more astonishing that it should ever have been lost sight of; yet that was the case, and on the revival of the art of painting the old original futile means of labels, &c. were had recourse to, till the gradual advance of learning and propriety of sentiment again restored it in the 15th century to the just imitation of the impressions of nature. Massaccio was among the first who thus advanced it, but it was Lionardo da Vinci who first perfected its claim to interest over the mind, though, perhaps, in none of his works so completely as in his representation of the Last Supper, painted on the walls of the refectory of the Dominican convent at Milan, where it shone for a period, unrivalled in truth and vigour of expression.

## EXPRESSION.

It represents the moment wherein our Saviour has just said to his disciples "One of you shall betray me." Each figure has intelligence beaming from it; each individual exhibits a full report of what passes within his bosom. How tranquilly, yet how fully does our Lord disclose this forerunner of his approaching miseries, that one of those whom he had loved and cherished should become treacherous, and turn his bounty to his ruin; and with what propriety is he thus represented tranquil, yet dignified! so consistent with his high character and office! With what eagerness does the impetuous Peter apply to the well designated meek and humble John, to learn the name of the culprit that would betray so good a master! while that conscious culprit, hearing the request, starts backward with alarm, fearing the consequences of such a disclosure. These are representations so powerful, that it needs but the regard of a moment to comprehend all said, and to be said, to complete the whole interest of the story. The timid hesitating Thomas, at a small distance from Peter, presses his hand on the other's shoulder, to urge him to make the request his own timidity prevents him from doing himself. The next of the apostles, whose peculiarities history hath not so fully recorded, are represented in great variety of actions and expressions corresponding with, and justly originating in, the incredible circumstance just announced to them. One, with his hands pressed on his bosom, rising, asserts his innocence; another starts with surprise, and, in the pious consciousness of sinful weakness, seems to demand "Lord, is it I?" One calmly, yet earnestly, listens to the result of the question urged by Peter: others, in contrast with him, seem to argue together if it be possible such iniquity could dwell with man, and in so doing declare their own innocence. Anxiety is depicted as disturbing every breast, yet the peculiarities of each are preserved with the most just discrimination; and all appear so impressed with nature, that while it is recognized as the offspring of that great man's genius, the mere imagination of his mind, it has the appearance of a portrait of the actual scene. It is now unfortunately much injured by time and cleaning, being painted in oil, and not, therefore, adhering to the wall so perfectly as fresco.

To become able to produce a work of this surprising power in expression, Lionardo says of himself, that he lost no opportunity which the occasions of life afforded him, of storing up remarks upon the nature of its action in men. He paid much attention to anatomy, and is said to have attended executions, not only to watch the looks and actions of the sufferers, but also to observe how the different persons composing the crowds of spectators were affected. The common occurrences of life are every day affording the attentive and ingenious artist lessons on this head; and he will succeed, accordingly as he is intelligent and active in observation of them; or if he neglects to improve his mind by them, is inattentive and unfeeling to them, he can never become equal to the task of representing them.

Michael Angelo was also a powerful promoter of this high quality in works of art, but his expression is of a grand and more mystic nature than Lionardo's, and it is Raffaele alone that has approached in his own way the superior excellencies of the work we have above described. "We stand in awe of Michael Angelo," says M. Fuseli, "while we embrace Raffaele, and follow him wherever he leads us." He has not succeeded well where he has attempted the sublime. His gods are not even heroes, and his heroes are common vulgar men, except in a few instances; but where tenderness, and the amiable qualities of human nature have been his subject, he is not behind his great

forerunner. Nor in the relation of his story is he ever deficient; sometimes, indeed, as has been observed on the Cartoon of Ananias struck dead, under the word ENERGY, in *Painting*, he combines the past events on which it depends, and the future, to which it leads. His Cartoons of "St. Paul preaching at Athens;" the "Healing the Lame Man at Lystra;" "Elymas struck blind," are instinct with feeling and expression: they are but slightly finished, and lack the extreme perfection of Lionardo's work; however, from the high degree of character to which Raffaele has carried some of his heads, in his picture of the "Transfiguration," 'tis fair to suppose he could have perfected these, if the nature of the works (being only examples for tapestry) had required it. In comparing the reputation of Raffaele to Lionardo da Vinci in this respect, it should not be forgot that he was only 36 years old when he died, and the latter was 49 or 50 when he painted the astonishing work of the "Last Supper." Had Raffaele lived to an advanced age, it is probable he would have surpassed even him. The simplicity and fullness with which he describes, or effects, the relation of his subject, is beautifully instanced in the Cartoons of "St. Paul and Barnabas healing the lame Man at Lystra," and the consequent adoration paid to them. The apostles are raised upon some steps above the croud, and thus distinguished, as well as by the attention of all being directed to them. The restored cripple is known from the rest, by his eager demonstrations of gratitude and adoration; by his united and uplifted hands and animated looks, addressed to his restorers, and by the crutches now become useless, and fallen at his feet to the ground. An aged man bending forwards, lifts with one hand the garments of the healed man, to view the limb now become perfect, and simply by the uplifting of the other, expresses his admiration of the cure so miraculously effected. It is the simplicity of the means Raffaele uses, which gives so much the appearance of nature to his expressions: no one, on seeing the works, doubts but that he should have employed the same means; the art is lost sight of. The effect of the pictures of Raffaele, in point of expression, on the artist who observes them, is much the same as Garrick's acting the character of a clown is said to have had upon a countryman, who completely lost sight of the actor, and criticized only the sentiments, in which, by the by, he complimented the author also, by stating that he should have done the same himself. Yet it is a fact, that no point in art is so difficult to attain as this true simplicity of character with effect. Perhaps the most beautiful piece of expression in painting known to the world, is Raffaele's head of the Madonna della Sedia, now in Paris. The sweetness of sentiment conveyed by the mouth is completely undefinable: no picture has been so frequently copied, none so rarely imitated.

Titian has frequently succeeded in rendering expression in his works, though it is not his general characteristic. His picture of St. Peter Martyr, before alluded to, (see EXECUTION, in *Painting*,) is almost perfect in this, as well as in most other points. Indeed, when taken in the whole, we cannot help considering this as the most perfect picture in the world; possessing more of every good quality than any other we are acquainted with. It has strongly the character of expression, both in form, and correspondent tone of colour. No man of feeling regards it, but with an instantaneous sentiment of seriousness; somewhat, indeed, of horror is inspired by the first view of it; particularly by the figure of the monk who is running away, and who eyes the proffered palm of martyrdom itself with horror. In direct opposition to him is the figure of the saint; who, suffering under the power of the

## EXPRESSION.

the assassin, (in whose person nought but the sentiment of brutality prevails,) turns his eyes towards the angels descending with the palm and crown, and hails the vision of future glory. The hue of the picture, we have said, is serious, and it is also rich and deep in colour; 'tis the effect of that hue which prevails at twilight, and is most judiciously chosen as suitable to the affecting nature of the subject. Raffaele has employed it in his portrait of Leo X. with the cardinals Rossi and Medici attending him. Here the subject was grand, and its effect is increased by the deep and serious tone of the colouring.

Poussin has, in several instances, been very happy in the expression of his subject. One of his pictures we will mention as a very excellent model of it; 'tis the Judgment of Solomon, a picture bad in its colour, in its composition, and execution, but fraught with the quality we are now considering. The king is seated upon his throne, surrounded by his attendants, and has just given the command to divide the living child. A soldier is proceeding to execute the order, and this gives occasion to the admirable display of diversity of feeling in the by-standers. An old man seems coolly to reason with himself if the king can intend the performance of so cruel a sentence. Another looks earnestly forward with the vacuity of aspect so commonly produced by surprise. A woman turns away her head to avoid the sight, and her child clings to her side alarmed. A soldier regards the scene with a countenance fraught with pity, another turns from it with disgust. Whilst the wicked, abandoned woman, who had slain her own child, seeks the destruction of her neighbour's also; the real mother implores, with an earnestness never to be too much admired, the preservation of her child; rather willing to disown, than to see it destroyed. The expression of the action of the king is completely that of conviction to whom the child belongs; he almost seems to exclaim, now I see the right, now I know to whom to give the award. Poussin has also in this instance added another useful indication of character in the attire of the woman, no less different in mind, than in habit. He has given to the vicious creature that negligence in dress which is too often indicative of a general habit of idleness and neglect; whilst he has dressed the other with decent care, and propriety.

This great painter has in another picture exhibited the force of colour in rendering expression, almost independent of form: 'tis in his picture of the deluge; one of a series of four pictures meant to represent the four seasons of the year. It is almost entirely of one hue. The composition consists of little more than a large portion of sky and water; the latter in the lower part of the picture falling in a cataract. In the distance is the ark, scarcely discernible through the thickness or dullness of vapour, through which the sun is with difficulty also seen, of a reddish hue. In the lowest corner of the picture is a family, consisting of a man, his wife, and child, endeavouring to climb from a boat upon a rock, on which a serpent glides along; and a little farther towards the centre are seen the heads of a man and horse just sinking in the water. With these slight materials has Poussin wrought a picture which is completely overpowering in its melancholy effect. It is said that Rousseau would sit enrapt in silence over it for hours, gratified with the sensations it inspired.

Another master, whose attempts to render expressions have been sometimes very successful, is Guido Rheni; but he seldom goes farther than the characters of saints in pious ejaculations, Magdalens in the moment of contrition, and Ecce Homo. Of the latter, there is one of super-excellent perfection, in the possession of B. West, esq. a head only, but full of feeling; surely "never was sorrow like unto his

sorrow," may be as justly applied to the painting, as to the sufferings of the divine original. There is an ancient painting of a Satyr's head, now in the Barberini palace at Rome, which is eminently distinguished by expression of character.

There are but few among the large mass of the Italian and French painters who have succeeded in their efforts (to any pre-eminent degree) in giving expression to their works in its more exalted sense. Ludovico Carrache, and Domenichino have sometimes effected it, but rarely, and Annibal Carrache still less frequently, notwithstanding his immense power in execution. Among the Flemings, Jan Steen, and Ostade, hold the principal places. The former particularly is exceedingly happy in characterizing the aspects and manners of that class of men he undertook to paint, and he does it with great freedom and ease. Ostade is more laboured in his manner, but perfect in his finish in the confused scale in which he exerted himself. Rubens has sometimes succeeded to a high degree in this quality, but, in general, the expressions of his figures in serious subjects are too violent, and outstep the modesty of nature. In the gayer scenes, where nymphs and fawns are fancifully indulging their humours, his power is complete; they live and breathe with all their native gaiety and animation; and in expressing the characters of beasts, either calm or enraged, not even Snyder has surpassed him. Vandyke rarely appears to have felt it in his historical pictures; but in some of his portraits he is extremely happy. His Cardinal Bentivoglio is a perfect instance of expression in this branch of art. His picture of lord Strafford and his secretary at Wentworth-house, Yorkshire, is another; but the idea is taken from Titian; whose portraits are master-pieces of identical character and expression, and the prototype of Vandyke's excellence. In this respect, sir Joshua Reynolds is no less happy than either of them: prints from whose pictures are in so many hands, and so generally known, that it is needless to exemplify the assertion by further remark, yet we cannot decline mentioning the picture of Mrs. Siddons in the character of the Tragic Muse, as a very happy instance of his power.

Rembrandt, though seldom happy in representing the purity of expression in his figures, yet sometimes effects it; but his great characteristic is the truth with which he gives expression in the secondary sense we have affixed to it, as regarding painting. To imitate the peculiarities of nature was his delight. He seized and expressed, with the greatest truth, the most extraordinary effects of the illumination of objects, and gave it its greatest possible brilliancy and force. In a different line, Netscher and Metzger were highly skilful in the exact expression of the nature of the objects they chose to represent. Silks, furs, carpets, metals, &c. all are expressed by them with the greatest truth, and in a free, broad style of execution, particularly by the former. Teniers, and in short almost all the painters of the Dutch and Flemish schools, have exhibited great ability in expressing the character of natural objects. But to this study they sacrificed attention to expression in its more elevated and useful province.

Not so our inimitable Hogarth. Though he took the common scenes of nature as his field of action; and was not unskilful in imitating the natural effect of objects; yet with him this meaner talent was of secondary consideration. By his pencil he inculcates lessons of morality, and no lectures from the pulpit are more effectually strong and convincing, than those conveyed by his pictures. Witness the Rake's, and the Harlot's Progress; where the evils attendant on vice, and the blessings which a course of virtue is calculated to produce, are so powerfully exemplified. With what force has he satirized pride and luxury in his Marriage-a-la-Mode; bigotry, superstition, and folly, in many of his other works!

and no one has ever expressed identical character more strongly than he has. The figure of the exhausted rake in the breakfast-scene of the *Marriage a-la-Mode*, has never been surpassed in truth and force. We could enlarge with pleasure upon his value in this point of view, but content ourselves with recommending his works with the excellent comments upon them by Mr. J. Ireland, to the perusal and observation of our readers; and are proud to have so excellent an exemplar of the value of expression in painting as Hogarth, whose talents were native, unindebted to foreign schools, in praise of whom to conclude our observations on this very important point.

**EXPROBATION, EXPROBATIO**, in *Rhetoric*, is the reproaching a person with ingratitude, and unmindfulness of some particular benefit conferred upon him.

**EXPUGNATION**, in *Military Language*, the taking of any place by assault.

**EXPULSION**, the act of driving a man by force out of a city, community, or the like.

**EXPULSION** is also used for the act of driving out a foreign body with violence from the place it was in.

The uterus has the chief office in the expulsion of the fœtus: if the expulsion of the fœtus happen very soon after conception, it is called a *false birth*. See **DELIVERY, FŒTUS**, and **LABOUR**.

**EXPURGATION**, in *Astronomy*, is used by some authors for that state or action of the sun, wherein, after having been eclipsed and hid by the interposition of the moon, it begins to appear again.

Later astronomers call this emersion, not expurgation.

**EXQUIMA**, in *Zoology*, the name of a species of monkey common on the coast of Guinea, of which Ray enumerates two or three varieties. See **SIMIA**.

**EXSIBIDANTES**, in *Antiquity*, a kind of dancers, who, in the theatre, and other public auditories, used to make a noise with their feet, and even sometimes beat the seats with battons.

**EXSICCATION**, formed of *ex* and *siccus*, dry, in *Chemistry, Pharmacy, &c.* the act of drying up or evaporating the moisture of a thing. For this purpose two methods are usually employed: in one of which the humidity is evaporated by heat, and in the other it is imbibed or absorbed by substances adapted to the purpose. Bodies combined with, or dissolved in a fluid, require the first mode, and to such as are only superficially blended with it, the second mode is applicable. Vegetables are commonly exsiccated by the natural warmth of the air, though the assistance of artificial heat is often very useful. By a moderate fire the more tender flowers may be soon dried without any considerable loss, either of their odour or lively colour, which would be injured, if not destroyed, by a more slow exsiccation in the air. Some plants, particularly those of the more acrid kind, lose their virtues by this process.

**EXSORS PARTICULA**. See **PARTICULA**.

**EXSUCCATIO**, a word used by some *Chirurgical Writers*, to express an enchymosis, or fuggillation.

**EXSUFFLATION**, a ceremony observed in baptism, by which the candidate was supposed to renounce the d. vil. See **BAPTISM**.

**EXTACY**, *ἔκστασις*, a rapture, or removal of the mind out of its natural state and situation; or a transport, whereby a person is hurried out of himself, and the office of his senses is suspended. See **ENTHUSIASM**.

**EXTACY**, in *Medicine*. See **ECSTASIS**.

**EXTANT**, something that still subsists, or is in being.

It is but part of the history of Livy, of the writings of

Cicero, Cæsar, &c. that are extant, the rest are lost. We have nothing extant of Socrates, though he wrote a great deal.

**EXTEMPORANEOUS PRESCRIPTION**. See **PRESCRIPTION**.

**EXTEMPORANEOUS Playing**, flights in *Music*, on a harpsichord, or piano forte, have many appellations; as toccata, toccatina, *Ital.* prelude, capriccio. On the organ it is called a voluntary.

There have been organists, whose abilities in un-studied effusions on their instruments have almost amounted to inspiration, such as Sebastian Bach, Handel, Marchand, Couperin, Kelway, Stanley, Worgan, and Keeble, several of whom played better music extempore, than they could write with meditation.

**EXTEND**, in the *Manege*. To extend a horse, is an expression used by some to import the same with making a horse go large. See **LARGE**.

**EXTEND**, in *Military Language*. When the files of a line, or the divisions of a column, are to occupy a greater space of ground, they are said to extend their front or line.

**EXTEND**, in *Law*. See **EXTENDING**.

**EXTENDENDA TERRA**. See **TERRA**.

**EXTENDI FACIAS**, in *Law*, a writ of extent, whereby the value of lands is commanded to be made and levied, &c. Reg. Orig. See **EXTENT**.

**EXTENDING**, in a *Legal Sense*, signifies the valuing of lands and tenements of one bound by statute, &c. and who hath forfeited his bond at such an indifferent rate, as that by the yearly rent the obligator may in time be fully paid his debt. See **EXTENT**.

**EXTENSION**, in *Philosophy*, is one of the general and essential properties of matter; the extension of a body being the quantity of space which the body occupies, the extremities of which limit, or circumscribe, the matter of that body. It is otherwise called the *magnitude*, or *size*, or *bulk* of a body.

A quantity of matter may be very small, or so as to elude the perception of our senses, such as a particle of air, a particle of water, &c.; yet some extension it must have, and it is by the comparison of this extension, that one body is said to be larger than, equal to, or smaller than, another body. The measurement of a body consists in the comparison of the extension of that body with some determinate extension, which is assumed as a standard, such as an inch, a foot, a yard, a mile; hence it is said, that a body is a foot long, or three inches long, &c.

The extension of a body is measured three different ways; or a body is said to have length, breadth, and thickness. Thus an ordinary sheet of writing paper is about 16 inches long, about 14 inches broad, and nearly one hundredth part of an inch thick. Either of these dimensions might be called the length, or the breadth, or the thickness; but, by general custom, the greatest extension is called the length, the next is called the breadth, and the shortest is called the thickness. The outside of a body, its boundary, or that which lies contiguous to other bodies that are next to it, is called the *surface* of that body, and this surface has two dimensions only, *viz.* length and breadth; but it has no thickness, for if it had, it would not be the outside of the body; yet a surface by itself cannot exist. In mathematics, however, surfaces are mentioned, and are reasoned upon, abstractly from matter. But in these cases the surfaces exist in the imagination only, and even then our ideas have a reference to body, for our senses cannot perceive a surface without a body.

As a surface is the outside or boundary of a body, so a

## EXTENSION.

*Line* is the boundary of a finite surface. Suppose, for instance, that a surface is divided into two parts, the common boundary of the two parts is called a line; and this has one extension only, *viz.* it has length.

The beginning, or the end of a line, or the intersection of two lines which cross each other, is called a *point*, and this has no dimensions; or, according to the mathematical definition, a point is that which has no parts or magnitude. Thus, if you divide a line into two parts, the division or boundary between the two parts is a point.

Our senses are only capable of perceiving bodies which have three dimensions; or rather the surfaces of bodies, which surfaces have two dimensions, but a surface cannot be represented nor perceived without a body, and of course neither a line nor a point can be perceived without a body. In the study of geometry, and in a variety of other branches, surfaces, lines, and points are represented upon paper, or upon something else; but in those cases, the paper or that something else is the body whose surface we perceive, and the surface of a particular figure is circumscribed, not by real lines, but by a narrow slip of surface, which is sufficient to direct our reasoning with respect to the geometrical properties of lines and surfaces. Thus also when points are represented by themselves, the marks are not real points, but very small portions of the surface of a body.

There is a case in which extension is often said to be perceived without the existence of a body, and this is the extension between two bodies. But, upon consideration, it will easily be comprehended, that we may perceive the two bodies, and that they are separate from each other; but we cannot perceive any thing positive between them. So that in this case the word extension is used in a figurative manner, as if some other body existed between the two bodies.

The particular extension, whether under the name of inch, foot, yard, metre, league, &c. with which other extensions are compared, or by which they are measured, are established only by the common consent or agreement of persons of a certain nation, or profession, and are used as standard measures by them only. Hence, the measures of different nations, though sometimes they have the same name, do, however, differ considerably from each other. Great endeavours have been made by divers ingenious persons, at different times, for the purpose of determining an unalterable universal standard of measures; but those endeavours, and the successes with which they have been attended, will be found described under the article *STANDARD of Measures*.

Extension is usually described as consisting in the situation of parts beyond parts, with which some authors cavil, maintaining, that we can conceive absolute extension without any relation to parts.

If a man consider the distance between two bodies abstractedly, and without any regard to bodies which may fill that interval, it is called space; and when he considers the distance between the extremes of a solid body, it is called extension.

Extension is frequently confounded with quantity and magnitude; and, for what we can perceive, without much harm, the thing signified by them all appearing to be the same; unless we admit a distinction made by some authors, that the extension of a body is something more absolute, and its quantity and magnitude more respective, or implying a nearer relation to much and little. See *QUANTITY*, *MAGNITUDE*, *MASS*, and *MATTER*.

The infinite divisibility of extension has been a famous question in all ages. It is not easy to reconcile the doc-

trine of mathematicians on this head with the tenets of some philosophers. They who hold that all extension and magnitude are compounded of certain *minima sensibilia*; and that a line, for instance, cannot increase or decrease, but by certain indivisible increments or decrements only, mult, consistently with themselves, affirm, that all lines are commensurable to each other, contrary to the tenth book of Euclid, who demonstrates that the diagonal of a square is incommensurable to its side. But if all lines were composed of certain indivisible elements, it is plain one of those elements must be the common measure of the diagonal and the side. This is a gordian knot which none of the philosophers have yet thought fit to untie.

Bishop Berkeley observes, that the infinite divisibility of finite extension, though it is not expressly laid down either as an axiom or theorem in the elements of geometry, yet is throughout the same every where supposed, and thought to have so inseparable and essential a connection with the principles and demonstrations in geometry, that mathematicians never admit it into doubt, or make the least question of it. (See *DIVISIBILITY*.) And as this notion is the source from whence do spring all those amusing geometrical paradoxes, which have such a direct repugnancy to the plain common sense of mankind, and are admitted with so much reluctance into a mind not yet debauched by learning; so is it the principal occasion of all that nice and extreme subtilty which renders the study of mathematics so difficult and tedious. Hence, says he, if we can make it appear, that no finite extension contains innumerable parts, or is infinitely divisible, it follows, that we shall at once clear the science of geometry from a great number of difficulties and contradictions which have ever been esteemed a reproach to human reason, and without make the attainment thereof a business of much less time and pains than it hitherto hath been.

Every particular finite extension, which may possibly be the object of our thought, is an idea existing only in the mind, and consequently each part thereof must be perceived. If therefore, says this author, I cannot perceive innumerable parts in any infinite extension that I consider, it is certain they are not contained in it; but it is evident, that I cannot distinguish innumerable parts in any particular line, surface or solid, which I either perceive by sense, or figure to myself in my mind; wherefore, I conclude they are not contained in it. Nothing can be plainer to me than that the extensions I have in view are no other than my own ideas; and it is no less plain, that I cannot resolve any one of my ideas into an infinite number of other ideas; that is, that they are not infinitely divisible. If by an infinite extension be meant something distinct from a finite idea, I declare I do not know what that is, and so cannot affirm or deny any thing of it. But if the terms extension, parts, and the like, are taken in any sense conceivable; that is, for ideas; then to say a finite quantity or extension consists of parts infinite in number, is so manifest a contradiction, that every one at first sight acknowledges it to be so. *New Theory of Vision*, § 54, 55. *Analyst*. § 31.

On the other hand, it is observed by an eminent mathematician, that geometers are under no necessity of supposing that a finite quantity or extension consists of parts infinite in number, or that there are any more parts in a given magnitude than they can conceive or express: it is sufficient that it may be conceived to be divided into a number of parts equal to any given or proposed number; and this is all that is supposed in strict geometry concerning the divisibility of magnitude. It is true, that the number of parts into which a given magnitude may be conceived

to be divided, is not to be fixed or limited, because no given number is so great but a greater than it may be conceived and assigned: but there is not therefore any necessity for supposing that number infinite; and if some may have drawn very abstruse consequences from such suppositions, they are not to be imputed to geometry. Geometricians are under no necessity of supposing a given magnitude to be divided into an infinite number of parts, or to be made up of infinitesimals; nevertheless, they cannot so well avoid supposing it to be divided into a greater number of parts than may be distinguished in it by sense in any particular determinate circumstance. But they find no difficulty in conceiving this; and such a supposition does not appear to be repugnant to the common sense of mankind, but on the contrary to be most agreeable to it, and to be illustrated by common observation. It would seem very unaccountable not to allow them to conceive a given line, of an inch in length for example, viewed at the distance of 10 feet, to be divided into more parts than are discerned in it at that distance; since by bringing it nearer, a greater number of parts is actually perceived in it. Nor is it easy to limit the number of parts that may be perceived in it when it is brought near to the eye, and is seen through a little hole in a thin plate? or, when by any other contrivance it is rendered distinct at small distances from the eye. If we conceive a given line that is the object of sight to be divided into more parts than we perceive in it, it would seem that no good reason can be assigned why we may not conceive tangible magnitude to be divided into more parts than are perceived in it by the touch; or a line of any kind to be divided into any given number of parts, whether so many parts be actually distinguished by sense, or not. In applying the reasonings and demonstrations of geometricians on this subject, it ought to be remembered, that a surface is not considered by them as a body of the least sensible magnitude, but as the termination or boundary of a body; a line is not considered as a surface of the least sensible breadth, but as the termination or limit of a surface; nor is a point considered as the least sensible line, or a moment as the least perceptible time; but a point as a termination of a line, and a moment as a termination of a limit of time. In this sense they conceive clearly what a surface, line, point, and a moment of time is; and the postulata of Euclid being allowed and applied in this sense, the proofs by which it is shewn, that a given magnitude may be conceived to be divided into any given number of parts, appear satisfactory; and if we avoid supposing the parts of a given magnitude to be infinitely small, or to be infinite in number, this seems to be all that the most scrupulous can require. See Maclaurin's Treatise of Fluxions-art, 290, 291.

Dr. Reid, in his "Inquiry into the Human Mind, on the Principles of Common Sense," endeavours to obviate the difficulties suggested by Berkeley, by overturning the system of ideas established by Mr. Locke. According to his theory, it is absurd to deduce from sensation the first origin of our notions of external existence, of space, motion, and extension, and all the primary qualities of bodies; they have, he says, no resemblance to any sensation, or to any operation of our minds, and therefore they cannot be ideas either of sensation or reflection; nor can he conceive how extension, or any image of extension, can be in an unextended and indivisible subject like the human mind.

EXTENSION, in the *Ancient Music*, according to Aristoxenus, was one of the four parts of the melopœia, which consisted in sustaining certain sounds longer than their quantity strictly required. We call these binding-notes, and sometimes perhaps tempo rubato. See COMPASS.

EXTENSION of *Fractured Limbs*. See FRACTURE.

EXTENSOR, in *Anatomy*, a name given to those muscles which have the use of extending or making straight those parts to which they are attached.

EXTENSOR *brevis digitorum pedis*; calcaneo-fus-phalangettien commun, is a thin and flat muscle, placed on the superior or convex surface of the foot. Possessing a somewhat quadrilateral figure behind, it divides into four flat tendons in front. It arises from the upper and front part of the os calcis, and from the ligament which connects that bone to the astragalus. Thence its fibres are continued obliquely forwards and inwards, and divide into four secondary fasciculi, (of which the two innermost are the largest,) giving origin to the same number of tendons; which, in passing over the metatarsus, cross those of the extensor longus, and terminate in the toes. The first, on the inside, is attached to the upper surface of the metatarsal extremity of the first phalanx of the great toe; the three succeeding tendons become intimately attached to the external edge of the corresponding tendons of the extensor longus, and are connected at the first joints of the toes, as well as those of the latter muscle, with the tendons of the lumbricales and interossei. They extend over the second phalanges, and are inserted in the third.

Covered on its external surface by the tendons of the extensor longus and peroneus tertius, and by the aponeurosis of the back of the foot, this muscle lies upon the anterior phalanx of the tarsus, upon the metatarsus, and the phalanges.

It extends and elevates all the phalanges of the toes, at the same time turning them rather outwards.

EXTENSORES *carpi radiales*. See CARPI.

EXTENSOR *carpi ulnaris*. See CARPI.

EXTENSOR *communis digitorum manus*; epicondylo-fus-phalangettien commun; extensive digital; a muscle belonging to the fingers, situated on the posterior or dorsal surface of the fore-arm, hand, and fingers; elongated, somewhat rounded and fleshy above, and divided into four tendons below.

It arises above, by means of a tendon common to it with the surrounding muscles, from the external condyle of the humerus; is connected internally to a tendinous partition, which separates it from the extensor of the little finger, externally to a shorter septum placed between it and the extensor carpi radialis brevis, and posteriorly to the fascia of the fore-arm. The fibres, uniting together obliquely from these origins, form a muscle, at first thin, and afterwards more considerable, which is divided, towards the middle of the fore-arm, into four portions, united at first by cellular substance, then separating, and giving origin to the same number of tendons. These at first are connected by a loose cellular substance, pass together with the tendon of the indicator under the annular ligament at the back of the wrist, and in a superficial groove of the radius, surrounded by a bursa mucosa, then diverge towards the fore fingers, and become completely flattened. They are often split longitudinally, and are united to each other, at the back of the hand, by cross slips of tendon and their aponeuroses. At the first joints of the fingers the broad thin tendons of the extensor communis are joined, on either side by the tendinous expansions of the lumbricales and interossei, and completely cover the articulation. They divide, at their extremities, into three portions, the middle of which are inserted in the second phalanges of the fore-fingers; while the lateral divisions, running along the sides of these phalanges, are inserted close together into the third.

This muscle is covered by the aponeurosis of the fore-arm,

## EXTENSOR.

the annular ligament and skin. It covers the supinator radii brevis, the extensors of the thumb and fore-finger, the carpus, metacarpus, interossei muscles, and posterior surface of the phalanges.

The annular ligament at the back of the fore-arm consists of a broad, thin, and flat, but strong fibrous expansion, extended from the outer part of the carpal extremity of the radius, over all the extensor tendons at the back of the wrist, and connected to the end of the ulna; and to the os pisiforme. It confines the tendons to the surface of the bones. Those of the common extensor are surrounded, as they pass under it, by a synovial membrane, in which we may distinguish a cavity containing the membranes completely isolated, and a superior and inferior cul de sac, where the membrane is reflected over the tendons. The synovial membranes of the first joints of the fingers are closely connected to the tendons of the extensor communis, where they pass over those joints.

This muscle extends the different joints of the fingers; and afterwards, or if the fingers are bent by their flexors, it extends the wrist upon the fore-arm.

*EXTENSOR indicis.* See INDICATOR.

*EXTENSOR longus digitorum pedis*; peroneo-tibi-fus-phalangettien commun; grand extenseur; is a long, thin muscle, flattened laterally, and placed at the outer and anterior part of the leg, and upper part of the foot. It arises above from the external tuberosity of the tibia, from a small aponeurotic septum which separates it from the tibialis anticus, and from the anterior ligaments of the peroneo-tibial articulation; behind from five or six inches of the upper and anterior part of the fibula; before, at its upper part, from the aponeurosis of the leg; and externally, from a broad aponeurotic septum, which separates it from the two peronei. The superior fibres descend perpendicularly, the inferior ones more and more obliquely, to end in a common tendon at first concealed in the substance, but, from the middle of the leg, occupying the anterior edge of the muscle. It divides into three or four portions, which pass together behind the annular ligament: below which part we always see four separate tendons diverging over the convexity of the foot, assuming a broad and flattened form, and crossing the direction of the tendons of the extensor brevis, in their passage to the four smaller toes. At the first joints of the toes these tendons are connected to those of the extensor brevis, and of the lumbricales and interossei, as in the hand, and they have similar insertions to those of the extensor communis digitorum, which see.

In the leg, this muscle, on its inner surface, is separated above by the anterior tibial vessels from the tibialis anticus; lower down it is contiguous, on the same aspect, with the extensor proprius hallucis; externally it is in contact with the peronei; and the aponeurosis of the leg covers it on the front. At the ankle it runs in a peculiar cavity of the strong transverse annular ligament, which binds it firmly down in its place. Here the tendons are surrounded by a synovial membrane. In the foot it is covered by the skin, and covers the extensor brevis and phalanges.

This muscle extends the toes, and afterwards bends the ankle joint. If the foot be fixed to the ground, it may either maintain the leg erect upon the foot, or carry it forwards.

*EXTENSOR longus pollicis pedis*; or *proprius*; peroneo-fus-phalangien du pouce; thin, elongated and flattened in its form, it lies on the inside of the preceding muscle. It arises from the inner and anterior part of the fibula, and neighbouring portion of the interosseous ligament, for a space of five or six inches, beginning about two inches

below the upper end of the fibula. Its fibres pass obliquely downwards and forwards, parallel to each other, and joining a tendon which runs along their anterior edge, constitute a single penniform muscle. The tendon goes behind the annular ligament, in a peculiar bursa mucosa, runs along the inner edge of the metatarsus, and passing over the first, terminates in the second phalanx of the great toe. Sometimes a small portion of its tendon is inserted in the first phalanx.

This muscle is placed between the tibialis anticus, the anterior tibial vessels and nerves being however interposed, and the extensor longus digitorum. On the front it is covered by the aponeurosis of the leg, the annular ligament, and the integuments. Its tendons lie on the lower end of the tibia, the tarsus, metatarsus, and phalanges of the great toe, and is closely connected to the synovial membrane of the first joint of that toe.

It extends the two joints of the great toe, and acts upon the foot in the same manner as the preceding muscle.

*EXTENSOR major pollicis.* See *EXTENSORES pollicis*.

*EXTENSOR minor pollicis.* See *EXTENSORES pollicis*.

*EXTENSOR ossis metacarpi pollicis.* See *EXTENSORES pollicis*.

*EXTENSORES pollicis*; are three muscles belonging to the three bones of the thumb.

*EXTENSOR primi internodii*; extensor ossis metacarpi pollicis; abductor pollicis longus of Albinus; cubito-radialis metacarpien du pouce; grand abducteur du pouce; is a muscle of an elongated, thin, and flattened form, situated obliquely on the back of the fore-arm. It arises above from the ulna, below the supinator radii brevis; from the interosseous ligament; and from the radius just below the insertion of the supinator brevis. The fleshy fibres unite together from these origins to form a flattened fasciculus at first small, but afterwards larger, which crosses the fore-arm obliquely from above downwards, and from the radial towards the ulnar side. Towards the lower extremity of the radius it terminates in a tendon, which runs in a small groove on the outer side of the carpal extremity of the bone. Here it is surrounded by a hollow bursa, common to it with the tendon of the next muscle. It is inserted, generally by means of several more or less distinct portions, into the radial side of the carpal end of the first phalanx of the thumb. One of these portions is often connected with the abductor pollicis.

It is covered, in its fleshy portion, by the extensor carpi ulnaris, extensor secundi internodii, extensor proprius auricularis, and communis digitorum; and it covers the radius, ulna and interosseous ligament. Its tendon is covered by the aponeurosis of the fore-arm, and covers the extensores carpi, the radius, radial artery, and joint of the wrist.

It extends the first bone of the thumb, when that has been bent towards the palm of the hand. It carries the thumb away from the other fingers; and it may move the whole hand towards the radius.

*EXTENSOR secundi internodii*; extensor minor pollicis; cubito-fus-phalangien du pouce; is an elongated and slender muscle, situated close to the former, and lying on its ulnar edge. Arising from the interosseous ligament and radius, it crosses the direction of the fore-arm, like the former, and forms a slender tendon, which closely accompanies that of the preceding muscle. It passes along the first, and is inserted in the second phalanx of the thumb. It is covered by the extensor tertii internodii, proprius auricularis, and digitorum communis, by the aponeurosis of the fore-arm, and the integuments. It lies upon the bones of the fore-arm and the interosseous ligaments, the extensores carpi radiales, the

joint

joint of the wrist, and the first bone of the thumb. It extends the first and second joints of the thumb, and carries it into the state of abduction. It may draw the whole hand towards the radius.

*EXTENSOR tertii internodii*; *extensor major pollicis*; *cutibito-sus-phalangettien du pouce*; is an elongated and slender muscle, placed close on the ulnar edge of the former, and following the same general direction. It arises from the middle third of the posterior surface of the ulna, and a very little from the interosseous ligament; and crosses the fore-arm obliquely towards the thumb. Surrounded by a hollow bursa, it runs along a peculiar groove of the radius, being placed about an inch on the ulnar side of the preceding tendons. It passes along the ulnar side of the first phalanx of the thumb; is connected with the insertion of the preceding tendon in the second phalanx, and terminates in the third. Situated at its origin between the bones of the fore-arm and interosseous ligament, and the *extensor communis*, *proprius auricularis*, and *carpi ulnaris*, it afterwards runs in its peculiar groove: it is then sub-cutaneous, and lies on the *extensores carpi*, joint of the wrist, and bones of the thumb. It extends all the joints of the thumb, and at the same time rather carries it towards the fingers. It will also act as an extensor of the wrist.

*EXTENSOR proprius auricularis*, or *digiti minimi*; *epicondylo-sus-phalangettien du petit doigt*; is a thin, slender, and elongated muscle, situated in the first or superficial layer of the back of the fore-arm, and placed close along the ulnar side of the *extensor digitorum communis*. It arises above by means of the common tendon, from the external condyle of the humerus; on the outside, from a septum, which separates it from the *extensor communis*; on the inside, from one interposed between it and the *flexor carpi ulnaris*; and behind, from the aponeurosis of the fore-arm. It gives origin to a slender tendon, which passes in a separate canal of the annular ligament, and forming the tendon which the little finger receives from the *extensor communis*, is inserted together with it into that finger. On the fore-arm, this muscle is covered by the fascia, and covers the *supinator brevis*, the *extensores* of the thumb, and the *indicator*. The *extensor communis* lies on its outside, and the *extensor carpi ulnaris* on the inside. Its tendon is surrounded by a tendinous sheath, lined with a synovial membrane, at the wrist; and afterwards is covered by the integuments lying on the last metacarpal bone, and on the phalanges of the little finger. It extends the little finger, and afterwards moves the wrist in the same direction; it will carry the little finger rather in the direction of abduction.

*EXTENSOR proprius pollicis pedis*. See *EXTENSOR longus pollicis pedis*.

*EXTENSOR tarsi minor*, a name given by Douglas to the plantaris, which see.

*EXTENSOR tarsi suralis*, or *magnus*; a name under which Douglas classes the *gastrocnemius* and *soleus*. See those words.

**EXTENT**, or **EXTENDI FACIAS**, in *Law*, sometimes denotes a writ or commission to the sheriff for the valuing of lands and tenements; sometimes the act of the sheriff or other commissioner upon this writ; and sometimes the estimate or valuation of lands, *per proprios viros*; which, when taken at the utmost value or extent, furnish our extended, or rack-rents. *Fleta*. lib. ii.

This is a species of *execution* (which see) upon some securities given by statute; as in the case of recognizances or debts acknowledged on statutes-merchant, or statutes-staple; upon forfeiture of which, the body, lands, and

goods may be all taken at once, to compel the payment of the debt. And by statute 33 Hen. VIII. c. 39. all obligations made to the king shall have the same force, and of consequence the same remedy to recover them, as a statute-staple; though, indeed, before this statute, the king was entitled to sue out execution against the body, lands, and goods of his accountant or debtor. (3 Rep. 12.) And his debt shall, in suing out execution, be preferred to that of every other creditor, who hath not obtained judgment before the king commenced his suit. The king's judgment also affects all lands, which the king's debtor hath at or after the time of contracting his debt, or which any of his officers, mentioned in the statute 13 Eliz. c. 4. hath at or after the time of his entering on the office; so that, if such officer of the crown alienes for a valuable consideration, the land shall be liable to the king's debt, even in the hands of a *bonâ fide* purchaser; though the debt due to the king was contracted by the vendor many years after the alienation. (10 Rep. 55, 56.) Whereas judgments between subject and subject reverted, even at common law, no farther back than the first day of the term in which they were recovered, in respect of the lands of the debtor; and did not bind his goods and chattels, but from the date of the writ of the execution: and now, by the statute of frauds, 29 Car. II. c. 3; the judgment shall not bind the land in the hands of a *bonâ fide* purchaser, but only from the day of actually signing the same; which is directed by the statute to be punctually entered on the record; nor shall the writ of execution bind the goods in the hand of a stranger, or a purchaser (Skin. 257.); but only from the actual delivery of the writ to the sheriff or other officer, who is therefore ordered to endorse on the back of it the day of his receiving the same. *Blackst.* Comm. book iii.

**EXTENUATION**, the act of diminishing or lessening the bulk or substance of a thing, especially of the human body. Fevers, agues, long abstinences; &c. occasion great extenuations or emaciations.

**EXTENUATION** is also a figure in *Rhetoric*, opposite to the hyperbole. The Greeks call it *λετομία*.

**EXTERIOR Polygon, Talus**. See the substantives.

**EXTERMINATION**, formed of *ex* and *terminus*, boundary, the act of extirpating, or totally destroying a people, race, family, &c.

The Jews have been exterminated out of Portugal, the Moors out of Spain, the Albigenes out of France, &c. Philip the Fair of France, to be revenged on the Knights Templars, took a resolution, in 1307, to exterminate them.

**EXTERMINATION**, or *Exterminating*, in *Algebra*, is used for taking away. Thus algebraists speak of exterminating surds, fractions, and unknown quantities out of equations. See *Maclaur.* *Algebr.* part i. chap. 12, where we have some general theorems for the exterminating unknown quantities in given equations. See **EQUATION**.

**EXTERNAL**, or **EXTERIOR**, a term of relation, applied to the surface or outside of a body; or that part which appears or presents itself to the eye, touch, &c. In which sense it is opposed to *internal* or *interior*.

The senses are divided into external, which are those whereby we perceive ideas, or have the perception of external objects; as seeing, hearing, &c. and internal. See **SENSE**.

**EXTERNAL** is also used to express any thing that is with-outside a man, or that is not within him, and particularly in his mind. In which sense we say external objects, &c.

The existence of an external world, *i. e.* of bodies and objects out of the mind, is a thing which has been greatly called

called in question by Dr. Berkeley and others. See **EXISTENCE**, **BODY**, and **QUALITY**.

**EXTERNAL Angles.** See **ANGLES**, *external*.

**EXTERNAL Denomination, Ear, Modes, Place.** See the substantives.

**EXTERNUS AURIS**, in *Anatomy*. See **EAR**.

**EXTERNUS Cubitus.** See **CUBITÆUS**.

**EXTERNUS Duverni**, a name given by Douglas to one of the muscles of the ear, called by Cowper and others *obliquus auris*, and by Albinus *externus mallei*. See **EAR**.

**EXTERNUS Gastrocnemius, Iliacus.** See the substantives.

**EXTERNUS Mallei.** See **EAR**.

**EXTERNUS Orbiter, Pterigoideus, Vastus, Rectus Capitis,** See the several articles.

**EXTINCTION**, the act of extinguishing, that is, of putting out, or destroying, fire, flame, or light.

The Aristotelians account for the extinction of fire from the principle of contrariety; thus, say they, water puts out fire, because the qualities of water are contrary to those of fire, the one being cold and moist, and the other hot and dry. But how far this will go, may appear hence, that fire is extinguished by hot water as readily as cold; nay, even by oil, earth, &c.

Some of the moderns offer two more plausible causes of extinction; *viz.* dissipation, as when the next immediate fuel of the flame is dispersed and blown off by too forcible a wind; and suffocation, when it is so compressed, that its free motion cannot be maintained; as happens upon throwing water, &c. thereon. Various preparations and engines have been contrived for extinguishing accidental fires. See **FIRE**.

Boerhaave denies that there is properly any such thing as extinguishing of fire; it is a body *sui generis*, of an immutable nature, and we can no more extinguish or destroy it than we can create it.

**EXTINCTION**, in *Chemistry* and *Pharmacy*, is when a metal, mineral, or the like body, after having been heated red-hot in the fire, is plunged in some fluid, either to soften or temper its acrimony, as tutty in rose-water; or to communicate its virtue to the liquor, as iron or steel to common water; or, lastly, to give it a temper, as in the extinction of steel in water, or some other preparation.

**EXTINGUISHER, SELF-ACTING**, is a contrivance whereby a candle can be extinguished at any given time after being lighted. There are several ways by which this can be effected. The most simple is placing the candle in a vessel of water, with such a length above the surface as will burn as long as a light is wanted; of course when the candle burns down to the water it will be extinguished.

*Figs. 10 and 11, Plate XII. Miscellany*, represent two neat mechanical contrivances for the above purpose; in *fig. 10*, *a a* is a brass clip, formed of two pieces, and jointed together by the pin, *b*, by means of a sliding ring, *d*; this clip can be closed round the candle so as to fix firmly thereto; the pin, *b*, has a joint in the upper end to receive a crooked lever, *e*, which has a conical extinguisher fastened at the other end of it. This extinguisher is held up from falling upon the candle, by means of a small wire, *f*, which is bent sideways at the end, and thrust into the candle, at the place where it is intended to be put out; as the tallow is consumed, it becomes so soft as to be unable to sustain the pressure of the wire, *f*, which therefore flies forward, and the extinguisher falls upon the candle. It must be observed that the wire, *f*, must only be put into the tallow, but not in the wick, as it might not then fall down quickly.

*Fig. 11* is another extinguisher, invented by Mr. J. J. Hawkins, and placed in his museum of mechanical inven-

VOL. XIII.

tions: *a a* is a pair of nippers, made of tinned iron plate, and jointed in the middle; between the outer ends a piece of watch-spring is fixed, which causes the ends, *b*, to close upon the candle, and thus hold the extinguisher on the candle. The centre-pin of the joint is long enough to serve for the centre of another clip, *b b*, which is exactly similar to the lower one, except that instead of the bow to embrace the candle, two wires, *c, c*, are fixed to the ends, to shut the extinguisher, which is composed of two flat plates, *f, f*, which open and shut upon the joint, *g*. The spring between the ends of the nippers, *b, b*, has a constant tendency to close the extinguisher, but is prevented from shutting by the candle. When the candle burns away, it becomes lost at the place where the extinguisher bites the spring; then shuts it up, and puts out the light.

**EXTINGUISHMENT**, in *Law*, is used for a consolidation. Thus, if a man, having a yearly rent due to him out of my lands, afterwards purchase the same lands; both the property and rent, becoming consolidated, or united in one possessor, the rent is said to be extinguished.

So, where a man has a lease for years, and afterwards buys the property, there is a consolidation of the property, and an extinguishment of the lease.

But if a man have an estate in land merely for life or years, and hath a higher estate in a fee-simple, in the rent, this rent is not extinguished, but in suspense for a time; for, after the term, the rent shall revive. (*Terms de Ley.*) See **RELEASE**.

So also, if there be lord mesne and tenant, and the lord purchase the tenancy, the mesnalty is extinct.

Likewise by purchasing of lands wherein a person hath common appendant, the common is extinguished. (*Cro. El. 594.*) A release of common in one acre, is an extinguishment of the whole common. *Showers's Rep. 350.*

And where a person hath common of vicinage, if he incloses any part of the land, all the common is extinct. (*1 Brownl. 174.*) If a man hath a highway appendant to land, and afterwards purchaseth the land wherein the highway is, the way is extinct: though it is held, that a way of necessity to a market or church, or to arable land, is not so extinguished. *11 Hen. VII. 25 Co. Litt. 155.*

**EXTINGUISHMENT of a copyhold** takes place on any act of the copyholder's, which denotes his intention to hold no longer of his lord, and amounts to a determination of his will. (*Hutt. 81. Cro. Eliz. 21. 1 Jon. 41.*) As if a copyholder in fee accepts a lease for years of the same land from the lord, or accepts an assignment of a lease made to another from the lessee, his copyhold is extinct. (*Moor. 184. 2 Co. 166. Godb. 11. 101.*) A copyhold estate is extinct whenever it becomes not demisable by copy. *Coke's Copyholder, 62.* See **COPY-HOLD**.

**EXTINGUISHMENT of debt** happens in a variety of cases. Thus, if a creditor accepts a higher security than he had before, or accepts a bond for a legacy, the first debt or legacy is hereby extinguished.

**EXTINGUISHMENT of liberties.** If liberties and franchises granted by the king, such as felon's goods, waifs, strays, wrecks, &c. (*9 Rep. 25.*) come again to the crown, they are extinct in the crown, and the king is seized of them *jure corona*: but if liberties of fairs, markets, or other franchises, and jurisdictions, be erected, and created by the king, they will not be extinguished, nor their appendances severed from the possession. *9 Rep. 25.*

**EXTINGUISHMENT of services.** If the lord purchases or accepts any part of the tenancy, out of which an entire service is to be paid or done, the service becomes thereby extinct; unless it be for the public good, or homage and

fealty, which are not subject to extinguishment. (6 Rep. 1. 105. Co. Litt. 149.) If the lord and another person do purchase the lands out of which he is to have services, they are extinct; also by severance of the services a manor may be extinguished. Co. Litt. 147. 1 And. 257. See T E N U R E.

EXTINGUISHMENT of ways. See EXTINGUISHMENT.

EXTIRPATION, formed of *ex* and *stirps*, root, the act of pulling up, or destroying, a thing to the very roots.

Among the prayers of the Romish Jubilee, there is one for the extirpation of heresy.

EXTIRPATION. This word, in *Surgery*, signifies the eradication of any disease, tumour, &c. by some manual operation, whether done with a cutting instrument, with caustic, with a ligature, or any other means.

Thus, the generality of tumours are extirpated with a knife; but some, which class as excrescences, or warts, are frequently extirpated with caustic, or with the ligature. The extirpation of polypi in the nose is, for the most part, accomplished with forceps, by which such tumours are pulled, or rather twisted off.

The art of extirpating encysted tumours with adroitness consists in dissecting the parts, surrounding the tumour, without wounding the cyst. If the latter accident occur, the contents frequently flow out, the cyst collapses, and the continuance of the dissection is attended with more difficulty. It is a great point to remove every particle of the cyst, and, hence, it is satisfactory to take it out entire, that is, without wounding it. When any portion remains behind, the wound will frequently not heal, in consequence of fungous granulations, arising from the diseased part. Unless the swelling be large, a single incision through the skin is sufficient; but, in other instances, it is advantageous to make

two cuts in this manner ( ) ; first, because it facilitates the removal of the tumour; secondly, because it prevents a redundancy of skin, which would take place, if none were removed, and would greatly retard the cicatrization of the wound.

After the operation, the edges of the wound are to be brought together with sticking plaster, and a compress and bandage are to be applied.

When the breast is affected with any disease of an incurable nature, the surgeon can sometimes extirpate the malady by cutting away the whole of the diseased parts.

If the disease be of a scirrhous or malignant nature, some particularity in the mode of operating is requisite. The surgeon ought, in this case, not to be content with merely removing parts, which are palpably and visibly diseased; but he should also endeavour to remove a certain quantity of the substance, which is in the immediate circumference of the disease. In scirrhus, every surgeon knows the propensity of the skin to be affected, and the frequent extension of white morbid bands into the surrounding adipose substance. These facts greatly confirm the propriety of making a free removal of the skin, whenever it is in the least discoloured, puckered, adherent to the swelling beneath, or in any way altered; and of taking away a good deal of the fat, in which scirrhous tumours are sometimes involved. When there are no reasons for supposing the disease of the breast to be any thing else than a mere sarcomatous enlargement, the removal of the skin must certainly be considered unnecessary. When cancer recurs, the skin is the first part in which it usually makes its appearance, and the skin of the nipple in particular. Hence, many surgeons always make it a rule to remove the latter part, when it is judged proper to take away any of the integuments.

The operation is usually performed as the patient is in a sitting posture, well supported by pillows and assistants.

The pectoral muscle is to be made tense by keeping the arm back, by means of a stick, placed transversely behind the back, in front of the two arms.

If none of the integuments are to be removed, a straight incision is to be made through them; the tumour is to be regularly dissected all round from the circumjacent parts; and, lastly, its base is to be detached from its connections, from above downward, till the whole is separated.

This is the mode of removing all simple tumours, which are not of a malignant nature, and which are not of an immense size.

When the tumour is of a malignant nature, and adherent to the skin and pectoral muscle beneath, the operator is to remove, at least, an inch or two of the fat on every side of the disease. The portion of the skin intended to be taken away must be included in two semi-circular incisions, which meet thus ( ) at their extremities; and when the base of

the tumour is to be detached, the surface of the pectoral muscle, wherever it is adherent to the tumour, is also to be removed.

It is sufficiently obvious, that the advantage of making the incision in the above manner consists in enabling the surgeon to bring the edges of the wound together after the operation, so as to form a straight line, and unite by the first intention.

The mere magnitude of a tumour frequently renders it highly judicious to take away a portion of the skin in the above method. If some were not removed, the dissection of the tumour would be exceedingly tedious; and, after the operation, the loose undistended skin would lie in folds, and form, as it were, a large pouch for the lodgment of matter.

The tumour being removed, the surgeon should examine the interior of the wound, in order to ascertain that no indurated part is left behind. If any hardness should be felt, it is proper to remove it. The surgeon should also examine the surface of every scirrhous tumour, immediately after it is taken out, for the purpose of knowing whether any of the white bands, shooting into the surrounding fat, have been divided; for, in this case, some portions have been left behind, and ought to be taken away. Their situation may easily be known, by considering the position of the tumour before the operation.

When the dissection of a swelling will occupy a considerable time, it is always judicious practice to tie every large artery as soon as it is divided. This remark is not meant to comprehend vessels of such a diameter, that though they bleed when first cut, they do not emit blood afterwards, so as to require a ligature. It was Desault's invariable method, in cutting out tumours, to tie every large artery before he continued the dissection.

When a tumour of the breast has been entirely detached, and the hemorrhage suppressed, the stick confining the arm backward is to be removed. Then if there are any diseased glands in the axilla, it is a very excellent plan to tie the pedicles, by which they are attached on the side towards the axilla, before attempting to cut the tumours completely away. It would be extremely difficult, after taking off the gland, to tie the little short artery which enters the swelling, almost immediately after it has quitted one of the thoracic arteries. The bleeding also, in consequence of the shortness of the vessel, and vicinity of its orifice to the thoracic arteries, would be exceedingly profuse, seeming rather

rather to arise from a wound of the latter vessels than of a small branch.

The celebrated Default used to pursue the practice above recommended; and sir Charles Blicke has long been in the habit of observing the same rule, in the numerous operations which he has performed with the utmost benefit to the afflicted, and well deserved honour to himself.

When the operation is finished, the skin of the wound is to be relaxed, and the edges of the incision brought together with strips of adhesive plaster. Proper compresses and bandages are next to be applied. Should the operation have been the removal of a diseased breast, the nearest arm should be kept completely at rest in a sling, as whenever it moves, it occasions a disturbance of the pectoral muscle, and, of course, of the wound. (First lines of the "Practice of Surgery," by Samuel Cooper.)

For the mode of extirpating a diseased testis, see CASTRATION.

The method of effecting the extirpation of polypi is to be described in the article POLYPUS.

Some observations are offered, under the head EXOSTOSIS, on the subject of extirpating tumours of the bones. The way in which a diseased eye ought to be cut out, will be hereafter explained. See EYE, *Extirpation of*.

For an account of the plan of extirpating certain excrescences, see EXCRESCENCE.

EXTIRPATIONE, in *Law*, a judicial writ, either before or after judgment, that lies against a person, who when a verdict is found against him for land, &c. doth maliciously overthrow any house, or extirpate any trees upon it. Reg. Jud. 13. 56.

EXTISPES, formed of *exta*, and *spicere*, of *spicio*, or *inspicere*, *I view, consider*, in *Antiquity*, an officer who viewed and examined the intrails of victims; in order to draw presages from them as to futurity.

This kind of divination, called extispicium, was much in vogue throughout Greece, where there were two families, the Jamidæ and Clytidæ, consecrated, or set apart, peculiarly for it.

It appears to have been very ancient, and was probably derived from the ancients. Vitruvius, cap. 4. lib. i. gives the following plausible account of its origin. He says that the ancients inspected the livers of those animals which frequented the places where they intended to build or encamp; and if they commonly found that the liver, to which they attributed sanguification, was injured, they concluded that the waters and nourishment collected near such places were not wholesome.

In Italy, the first extispices were the Etrurians or Tuscan; among whom, likewise, the art was in great repute. Lucan gives us a fine description of one of these operations in his first book.

EXTORTION, in *Law*, denotes generally any oppression under colour of right; and it is usually applied to signify an illegal manner of wresting any thing from a man, either by force, menace, or authority: *e. g.* if an officer, by terrifying another on pretence of his office, or "by colour of his office," takes more than his ordinary fees or dues, he commits, and is indictable for, extortion.

So the exacting of unlawful usury, winning by unlawful game, and, in fine, all taking of more than is justly due, by colour or pretence of right, as excessive tolls in millers, excessive prices of ale, bread, victuals, wares, &c. come under extortion.

Crompton says, that wrong done by any man is properly a trespass, but excessive wrong is extortion; which is most properly applicable to sheriffs, mayors, bailiffs, and

other officers, who, by colour of their office, greatly oppress and wrong the king's subjects, by taking excessive reward, or fees, for executing their office: and extortion has been deemed more odious than robbery, because it carries an appearance of truth; and is often accompanied with perjury in officers, &c. by violating their oaths of office. The distinction between bribery and extortion seems to be this: the former offence consists in the offering a present, or receiving one if offered; the latter, in demanding a fee, or present, by colour of office. Extortion by the common law is severely punished, on indictment, by fine and imprisonment, and removal of officers from the offices in which the crime was committed. By the stat. 3 Edw. I. inferior officers of justice, &c. guilty of extortion, are to render by c. 26. double, and by c. 30. treble, value; and there are divers other statutes for punishing extortions of sheriffs, bailiffs, gaolers, clerks of the assize, and of the peace, attorneys and solicitors, &c. stats. 23 H. VI. c. 7 & 9. 33 H. VIII. c. 24. 29 Eliz. c. 4. 1 Jac. I. c. 10. 9 & 10 W. III. c. 41. 10 & 11 W. III. c. 23. 3 Geo. I. c. 15. 17 Geo. III. c. 26. § 6. In cases of extortion, there must be a positive charge, that the charged person did it *extorsivè*, or *colore officii*. The place where it was committed must be set down in the declaration; the sum extorted particularly specified, and the indictment or information must state the full particulars by specifying the time, &c. Against attorneys for extortion, action may be brought, and the party aggrieved shall have treble damages and costs; but information will not lie on the stat. 3 Jac. I. c. 7. Sid. 434. 4 Nels. 822.

EXTRA-Constellary Stars. See SPORADES.

EXTRA-judicial, something done out of the proper court, or the ordinary course of law. As when judgment is given in a cause, or case, not depending in that court where such judgment is given, or wherein the judge has no jurisdiction.

EXTRA-mundane space, is the infinite empty void space, which is by some supposed to be extended beyond the bounds of the universe, and consequently in which there is really nothing at all.

EXTRA-parochial, a place out of the bounds of any parish; or privileged and freed from the duties of a parish.

EXTRACT, in *Chemistry*. The term extract, as used in chemical nomenclature, has been borrowed from the pharmaceutical dispensaries, where it has long been applied to a great variety of substances which have little other agreement than in the mode of preparation, which consists in extracting by water, or any other menstruum, the soluble part of certain parts of vegetables, and inspissating this solution by heat to a thick consistence, or sometimes to entire solidity.

The term extract, therefore, in its original and pharmaceutical sense, only refers to the mode of preparation, and not to the nature of the substance prepared; and hence much confusion and uncertainty have prevailed in the attempts of chemists to define the nature of the substance to which this term should in strictness be limited.

All the pharmaceutical extracts are extremely compounded, for being prepared either by water or alcohol, of course every thing soluble in these liquids would be confounded in the general mass. Hence we find in one or other, and sometimes in a single extract, mucilage, sugar, tannin, gallic acid, resin, gluten, several neutral salts, and other ingredients. But along with these there always is found a considerable quantity of a brown tenacious substance, often with a bitter taste, and possessing a number of chemical properties, which entitle it to be considered as a peculiar sub-

## EXTRACT.

stance, and to which the term extract, or extractive principle, has been given.

The distinguishing properties of this substance have been laid down with much ability by Vauquelin, in his memoir on the extractive principle (*Journal de Pharmacie*, p. 132.) and in his researches on the sap and native juices of trees (*An. Chem.* tom. 31.) and also by Fourcroy in an elaborate and excellent analysis of the cinchona of St. Domingo. *An. Chem.* tom. 8 & 9.

We shall first notice the experiments of Vauquelin, which being made on the native juices of plants, the extract already in solution, and unaltered by the heat requisite in artificial decoction, is probably in a purer state.

When the sap of any tree is first drawn it is always colourless, or nearly so, but when inspissated by heat, however moderate, it always assumes a brown colour, and in the process of evaporation a certain though small quantity of pulverulent brown insoluble matter falls down. If this is collected separately before the juice is entirely inspissated, and treated with muriatic acid, one portion dissolves with effervescence, and is found to be chiefly carbonate of lime, and an insoluble part remains, which is considered by this excellent chemist as extract altered and oxygenated during the evaporation. If the concentrated sap is now slowly evaporated to dryness, it yields a brown extract, strongly deliquescent, and of a pungent saline taste. This entire extract is always extremely compounded, containing in fact all the soluble ingredients of the original juice. Gallic acid, when present, is detected by a solution of iron; tannin, by a solution of isinglass; salts of lime, by oxalic acid; sugar, by the taste, and by its soon acquiring the vinous fermentation. The entire extract also always contains acetic acid, partly in excess and partly united both to lime, potash, and ammonia, and hence when a few drops of strong sulphuric acid are poured upon any extract, copious vapours of pungent acetic acid are given out; and if this is done with large quantities, and in close vessels, acetic acid may be obtained pure. It is probably owing to the presence of these neutral acetites, that all the inspissated native juices attract moisture strongly from the air, and hence too their great disposition, to mould and change by keeping.

Ammonia also is detected in most inspissated juices of plants by the pungent vapours of this alkali, that are perceived on the addition of quick-lime, but in the natural state the ammonia is more than neutralized by the acetic acid, as all the soft extracts redden betimes.

Extractive matter (meaning by this term the pure extract) appears to form a great portion of the colouring matter of vegetables. If to any liquid containing extract a solution of alum be added, a copious coloured insoluble precipitate is produced, consisting chiefly of alumine in intimate combination with extractive matter, and the supernatant liquor remains clear and nearly colourless. The same process takes place in dyeing, the alum being first fixed on the cloth as a mordant, as it is called. The solutions of tin possess this power of precipitating coloured extract as an insoluble powder in a still more striking manner. That of the other metallic salts produce a similar precipitate of extract, combined with the metallic oxyd.

The experiments of Fourcroy on the cinchona have been detailed at length under that article, to which we refer our readers. It may be observed in this place, that the facts relative to the subject of extract were, shortly, that the decoction of cinchona during evaporation deposited a quantity of black matter, insoluble in cold water, but which mostly was dissolved in alcohol, leaving however a portion of a red powder of a peculiar nature, which the author of

the experiments considers as extractive matter, changed by union with oxygen, and thereby rendered insoluble in water or alcohol. The appearance of this powder, and its insolubility in water, might at first lead to the supposition that it was resin, but its equal insolubility in alcohol refutes this idea.

The precise nature of this insoluble matter, which is deposited on the evaporation of all vegetable infusions or decoctions, is hitherto not known, and several objections to the opinion of its being merely oxygenated extract may be adduced, which we have already detailed under the article CINCHONA.

On the whole, however, we may safely admit, that there is a peculiar substance found in almost all soluble matter of vegetables, and particularly in the common circulating juices, to which the term extract, or pure extractive principle, has been given, and which has the following distinguishing properties.

In its natural state in the sap of trees it is colourless, or nearly so; but when the solution is heated and inspissated, it always acquires a deep colour, which is generally brown or fawn, with various shades, and by the same process its solubility in cold water is diminished.

It is in its natural state equally soluble in alcohol as in water, by which circumstance it is distinguished both from pure mucilage and resin.

It is insoluble in ether.

It has a very strong affinity with alumine, and with metallic oxyds, and when combined with ether it becomes insoluble in water, alcohol, and many other menstrua. By destructive distillation it is resolvable into carbon, oxygen, and hydrogen, and a small proportion of azot.

Much variety is found in the properties of smell, taste, and colour, in the various extracts, and we are still totally ignorant how far these varieties may depend on other admixtures, or whether there are different species of extract; and in general we may add that this substance appears to be one which most easily enters into intimate combination with all the other soluble vegetable principles, and, consequently, can hardly by any known means be obtained pure, as it exists in the vegetable itself, and unchanged by the processes of analysis.

**EXTRACT, in Pharmacy.** The greater number of pharmaceutical extracts are made by boiling the substance (in coarse powder) in water, straining the decoction, boiling it down till it is considerably concentrated, then gently drying the residue in a stove, or slow oven, to the requisite consistence.

A few of the extracts are made with alcohol instead of water, or with a mixture of the two; the substance being first digested with the alcohol, and the tincture, thus prepared, strained off; the residue then boiled with water, and the decoction poured off, and both the decoction and tincture mixed, and evaporated slowly.

The purely spirituous extracts are also called resins, and are always evaporated to dryness, when they remain hard brittle masses, with a vitreous fracture, resolvable in alcohol, and in all essential characters resembling the natural resins.

In preparing the extracts by water the decoctions are usually directed to be set aside for some hours, that any sediment may be deposited, which last is to be rejected. But this is obviously a bad practice, as in many cases much of the medicinal property of the plant resides in this residue which subsides from the hot decoction on cooling.

Another species of extracts is the inspissated juices of plants. Several powerfully medicinal plants, such as the hemlock, are succulent vegetables, which, when strongly expressed,

expressed, yield a large quantity of a green turbid juice, which (after separating the mere fragments of the plant) only requires to be inspissated by a very gentle heat, to form the extract in the form in which it is used.

All the extracts, except those made by alcohol, are liable to spoil by keeping. This is particularly the case with the inspissated juice of the succulent plants, being composed of materials all extremely liable to fermentation, and being kept in a constant tendency to deliquescence by the neutral acetites which they contain. Therefore they must be kept in close vessels, but with every care the most important of them lose their medicinal quality in no great length of time.

EXTRACT, in *Matters of Literature*, denotes a short abridgment of a book or paper, or of some of the matters thereof. The journals, nouvelles, bibliothèques, mémoires, and other monthly reviews, or quarterly accounts of the affairs of learning, consist principally of extracts of the most material passages, doctrines, &c. found in the several books published in that time.

EXTRACT *ab Ecclesia*. See RESTITUTIONE *Extracti*.

EXTRACTA CURIÆ, in our *Old Writers*, the issues or profits of holding a court, arising from the customary fees, &c.

EXTRACTION, in *Pharmacy and Chemistry*, an operation, whereby essences, tinctures, &c. are drawn from natural bodies. See EXTRACT.

EXTRACTION, in *Surgery*, is the drawing from, or out of the body, any thing fixed in it, as a thorn, or bullet, in the flesh, a tooth from the jaw, &c. Surgeons speak also of the extraction of a stone from the bladder, a cataract from the eye, foreign bodies from the œsophagus, extraneous substances from wounds, &c. For a description of the methods of extracting a stone from the bladder, see LITHOTOMY.

The operation of extracting the cataract is explained in the article CATARACT.

EXTRACTION, or *Descent*, in *Genealogy*, denotes the stock, or family, which a person is descended from.

In some military orders, chapters, &c. a candidate must make proof of the nobility of his extraction before he is admitted.

EXTRACTION of *Roots*, the method of finding the roots of given numbers, or quantities. See ROOT.

The square, cube, and other powers of a number, or root, are formed by multiplying the given number into itself a greater or less number of times, as the power required is higher or lower. See POWER.

This multiplication compounds the powers; and the extraction of the roots decomposes them again, or reduces them to their principles or roots. So that the extraction of the root is to the multiplication of the power, what the analysis is to the synthesis.

Thus, 4, multiplied by 4, produces 16; which is the square of 4, or the factum of 4, by itself; and 16 multiplied by 4, makes 64, which is the cube of 4, or the factum of 4 by its square. Such is the composition of powers.

Again, the square root of 16 is 4, because 4 is the quotient of 16 divided by 4; and the cube root of 64 is likewise 4, as 4 is the quotient of 64 divided by the square of 4. Such is the extraction of roots.

Hence to extract the root out of a given power, is the same thing as to find a number, *e. gr.* 4, which being mul-

tipled a certain number of times into itself, produces the given power, *e. gr.* 16 or 64.

For the extraction of square and cube roots, it is necessary to have the squares and cubes of all the digits in readiness; as exhibited in the following table.

Roots	1	2	3	4	5	6	7	8	9
Square	1	4	9	16	25	36	49	64	81
Cube	1	8	27	64	125	216	343	512	729

To extract the square root out of a given number.—1. Divide the given number into classes, of two figures a-piece; and include each class between two dots, commencing with the place of units, and proceeding to the left in integers, and to the right in decimals; the root will consist of so many parts or figures as you have classes. By the way observe, it may happen, that for the last class on the left hand there shall be only one figure left.

2. Then the left-hand class being the square of the first figure of the root sought, look in the table of roots for the square root answering to that number; or, if that square number be not precisely there, to the next lesser number: this root write down for the first figure of the quotient; and subtract its square from the left-hand class. To the remainder bring down the next class toward the right.

3. Write down the double of the quotient figure under the left-hand figure of the second class; and seek how oft this double is contained in the figure over it: the quotient gives the second figure of the root.

4. Write the same quotient under the right-hand figure of the same class, and subtract the product of the whole number underwritten, multiplied by the second figure of the root, from the number over it, as in division.

5. The operation being repeated according to the third and fourth steps, *i. e.* the remainder being still divided by the double of the root as far as extracted; and from the remainder subtract the product of the last divisor, having the last found figure of the quotient added to it, multiplied by this figure, you will have the root required.

*E. gr.* To extract the root of 99856; point it after the following manner, 99856̇: then seek a number, whose square shall equal the first figure 9, *viz.* 3, and write it in the quotient; then having subtracted from 9, 3 × 3, or 9, there will remain 0; to which set down the figures as far as the next point, *viz.* 98, for the following operation. Then, taking no notice of the last figure 8, say, How many times is the double of 3, or 6, contained in the first figure 9? Answer, 1. Wherefore, having written 1 in the quotient, subtract the product, of 1 × 61, or 61 from 98, and there will remain 37, to which connect the last figures 56, and you will have the number 3756, in which the work is next to be carried on. Wherefore, also neglecting the last figure of this, *viz.* 6, say, How many times is the double of 31, or 62, contained in 375 (which may be guessed at from the initial figure 6 and 37, by taking notice how many times 6 is contained in 37)? Answer 6; and writing 6 in the quotient, subtract 6 × 626, or 3756, and there will remain 0; whence it appears, that the business is done, the root coming out 316.

Otherwise,

$$\begin{array}{r}
 99856 \overline{) 316} \\
 \underline{9} \phantom{00} \\
 098 \phantom{00} \\
 \underline{61} \phantom{00} \\
 3756 \phantom{00} \\
 \underline{3756} \\
 0
 \end{array}$$

# EXTRACTION.

Otherwise, with the divisors set down, it will stand thus :

$$\begin{array}{r}
 99856 \text{ (316)} \\
 \underline{9} \\
 6) 98 \\
 \underline{61} \\
 62) 3756 \\
 \underline{3756} \\
 0
 \end{array}$$

o And so in others.

Again, if you were to extract the square root out of 22178791 :

$$\begin{array}{r}
 22178791 \text{ (4709, 43637, \&c.)} \\
 \underline{16} \\
 617 \\
 609 \\
 \hline
 88791 \\
 84681 \\
 \hline
 411000 \\
 376736 \\
 \hline
 3426400 \\
 2825649 \\
 \hline
 60075100 \\
 56513196 \\
 \hline
 356190400 \\
 282566169 \\
 \hline
 73624231
 \end{array}$$

First having pointed it, seek a number, whose square (if it cannot be exactly equalled) shall be the next less square (or nearest) to 22, the figures to the first point, and you will find it to be 4. For  $5 \times 5$ , or 25, is greater than 22; and  $4 \times 4$ , or 16, is less; wherefore 4 will be the first figure of the root. This, therefore, being writ in the quotient, from 22 take the square  $4 \times 4$ , or 16; and to the remainder 6, adjoin the next figures 17, and you will have 617; from whose division, by the double of 4, you are to obtain the second figure of the root, viz. neglecting the last figure 7, say, how many times is 8 contained in 61? Answer, 7; wherefore write 7 in the quotient, and from 617 take the product of 7 into 87, or 609, and there will remain 8, to which join the two next figures 87, and you will have 887; by the division whereof by the double of 47, or 94, you are to obtain the third figure; in order to which say, how many times is 94 contained in 88? Answer, 0; wherefore write 0 in the quotient, and adjoin the two last figures 91, and you will have 88791, by whose division by the double of 470, or 940, you are to obtain the last figure; viz. say, how many times 940 in 8879? Answer, 9; wherefore write 9 in the quotient, and you will have the root 4709. But since the product  $9 \times 9409$ , or 84681, subtracted from 88791, leaves 4110, the number 4709 is not the root of the number 22178791 precisely, but a little less.

If then it be required to have the root approach nearer, carry on the operation in decimals, by adding to the remainder two cyphers in each operation. Thus, the remainder 4110, having two cyphers added to it, becomes 411000; the division whereof, by the double of 4709, or 9418, will give the first decimal figure 4. Then having writ 4 in the quotient, subtract  $4 \times 94184$ , or 376736, from 411000, and there will remain 34264. And so having added two more cyphers, the work may be carried on at pleasure, the root at length coming out 4709, 43637, &c.

But when the root is carried on half way or above, the rest of the figures may be obtained by division alone: as

in this example, if you have a mind to extract the root to nine figures, after the five former 4709,4 are extracted, the four latter may be had, by dividing the remainder by the double of 4709,4.

Thus if the root of 32976 were to be extracted to five places, in numbers; after the figures are pointed, write 1 in the quotient, as being the figure of whose square  $1 \times 1$ , or 1, is the greatest that is contained in 3, the figure to

$$32976 \text{ (181,59)}$$

$$\begin{array}{r}
 1 \\
 \hline
 2) 229 \\
 \underline{224} \\
 36) 576 \\
 \underline{361} \\
 362) 215(59, \&c.
 \end{array}$$

the first point; and having taken the square of 1 from 3, there will remain 2; then having set the two next figures, viz. 29, to it (viz. to 2,) seek how many times the double of 1, viz. 2, is contained in 22, and you will find indeed that it is contained more than ten times; but you are never to take your divisor 10 times, nor even 9 times in this case;

because the product of  $9 \times 29$ , or 261, is greater than 229, from which it would be to be taken, or subtracted; wherefore write only 8. And then having written 8 in the quotient, and subtracted  $8 \times 28$ , or 224, there will remain 5; and having set down to this the figures 76, seek how many times the double of 18, or 36, is contained in 57, and you will find one, and so write 1 in the quotient; and having subtracted  $1 \times 361$ , or 361, from 576, there will remain 215. Lastly, to obtain the remaining figures, divide this number 215, by the double of 181, viz. 362, and you will have the figures, 59 which, being writ in the quotient, give the root 181,59. After the same manner are roots extracted out of decimal numbers. Thus the root of 329,76 is 18,159; and the root of 3,2976 is 1,8159, and the root of 0,032976, is 0,18159, and so on. But the root of 3297,6 is 57,4247; and the root of 32,976 is 5,74247. And thus the root of 9,9856 is 3,16.

To extract the other, or higher root, out of a given number.

—The extraction of the cubic root, and all other roots, may be comprehended under one general rule; viz. every third figure, beginning from unity, is first to be pointed, if the root to be extracted be a cubic one; or every fifth, if it be a quadrato-cubic (or of the fifth power;) and then such a figure is to be writ in the quotient, whose greatest power (that is, whose cube, if it be a cubic power, or whose quadrato-cube, if it be the fifth power, &c.) shall either be equal to the figure, or figures, before the first point, or next less under them; and then having subtracted that power, the next figure will be found by dividing the remainder augmented by the next figure of the resolvend, by the next least power of the quotient multiplied by the index of the power to be extracted, that is, by the triple square, if the root be a cubic one; or by the quintuple biquadrate, (that is, five times the biquadrate,) if the root be of the fifth power, &c. And having again subtracted the power of the whole quotient from the first resolvend, the third figure will be found by dividing that remainder, augmented by the next figure of the resolvend, by the next lesser power of the whole quotient, multiplied by the index of the power to be extracted.

Thus, to extract the cube root of 13312053, the number is first to be pointed after this manner, viz. 13312053 then you are to write the figure 2, whose cube is 8, in the first place of the quotient, as that which is the next lesser

# EXTRACTION.

lesser cube to the figure 13, (which is not a perfect cube number) or as far as the first point; and having subtracted that cube, there will remain 5; which being augmented by the next figure of the resolvent 3, and divided by the triple square of the quotient 2, by seeking how many times 3 x 4, or 12, is contained in 53, gives 4, or the second figure of the quotient. But since the cube of the quotient 24, viz. 13824, would come out too great to be subtracted from the figures 13312, that precede the second point, there must only 3 be writ in the quotient; then the quotient 23 being in a separate place multiplied by 23, gives the square 529, which again multiplied by 23, gives the cube 12167; and this taken from 13312, will leave 1145, which augmented by the next figure of the resolvent 0, and divided by the triple square of the quotient 23, viz. by seeking how many times 3 x 529, or 1587, is contained in 11450, gives 7, for the third figure of the quotient. Then the quotient 237, multiplied by 237, gives the square 56169, which again multiplied by 237, gives the cube 13312053; and this taken from the resolvent, leaves 0. Whence it is evident, that the root sought is 237.

So also, to extract the quadrato-cubical root of 36430820, it must be pointed over every fifth figure; and the figure 3, whose quadrato-cube, or fifth power 243, is the next lesser to 364, viz. to the first point, must be writ in the quotient. Then the quadrato-cube 243 being subtracted from 364, there remains 121, which augmented by the next figure of the resolvent, viz. 3, and divided by five times the biquadrate of the quotient, viz. by seeking how many times 5 x 81, or 405, is contained in 1213, gives two for the second figure. That quotient 32 being thrice multiplied by itself, makes the biquadrate 1048576; and this again, multiplied by 32, makes the quadrato-cube 33554432, which, being subtracted from the resolvent, leaves 2876388. Therefore 32 is the integral part of the root but not the true root; wherefore, if you have a mind to prosecute the work in decimals, the remainder, augmented by a cypher, must be divided by five times the aforesaid biquadrate of the quotient, by seeking how many times 5 x 1048576, or 5242880, is contained in 28763880, and there will come out the third figure, or the first decimal 5. And so by subtracting the quadrato-cube of the quotient 32,5, from the resolvent, and dividing the remainder by five times its biquadrate, the fourth figure may be obtained. And so on *in infinitum*.

In some cases it is convenient only to indicate the extraction of a root, especially where it cannot be had exactly. Now, the sign or character whereby roots are denoted, is  $\sqrt{\quad}$ ; to which is added, the exponent of the power, if it be above a square, and even sometimes if it be not. *E. gr.*  $\sqrt{\quad}$  denotes the square root;  $\sqrt[3]{\quad}$  the cube root, &c. See **Root**.

When a biquadratic root is to be extracted, you may extract twice the square root, because  $\sqrt[4]{\quad}$  is as much as  $\sqrt{\quad} \times \sqrt{\quad}$ . And when the cubo-cubic root is to be extracted, you may first extract the cube root, and then the square root of that cube root, because the  $\sqrt[6]{\quad}$  is the same as  $\sqrt[3]{\quad} \times \sqrt[2]{\quad}$ ;

whence some have called these roots, not cubo-cubic ones but quadrato-cubes. And the same is to be observed in other roots, whose indices are not prime numbers.

To prove the extraction of roots.—1. For a square root; multiply the root found by itself, and to the product add the remainder, if there were any: if the sum be equal to the number given, the operation is just.

2. For a cube root. Multiply the root found by itself, and the product, again, by the same root. To the last product, add the remainder, if there were any. If the sum come out the number first given, the work is just.

After the like manner may the extraction of the other roots be proved.

To extract the roots of equations, or algebraic quantities.—The extraction of roots out of simple algebraic quantities, is evident, even from the nature, or marks of notation itself; as that  $\sqrt{aa}$  is  $a$ , and that  $\sqrt{aacc}$  is  $ac$ , and that  $\sqrt{9aacc}$  is  $3ac$ ; and that  $\sqrt{49a^2xx}$  is  $7aax$ .

And also that  $\sqrt{\frac{a^2}{cc}}$ , or  $\frac{\sqrt{a^2}}{\sqrt{cc}}$  is  $\frac{aa}{c}$ , and that  $\sqrt{\frac{a^2bb}{cc}}$  is  $\frac{aab}{c}$ , and that  $\sqrt{\frac{9aazz}{25bb}}$  is  $\frac{3az}{5b}$ , and that  $\sqrt{\frac{8b^6}{27a^3}}$  is  $\frac{2bb}{3a}$ , and that  $\sqrt[4]{aabb}$  is  $\sqrt{ab}$ ;

moreover, that  $b\sqrt{aacc}$ , or  $b$  into  $\sqrt{aacc}$ , is equivalent to  $b$  into  $ac$ , or  $abc$ ; and that  $3c\sqrt{\frac{9aazz}{25bb}}$  is equivalent to  $3c \times \frac{3az}{5b}$ , or  $\frac{9acz}{5b}$ . And that  $\frac{a+3x}{c} \sqrt{\frac{4b^2x^2}{81aa}}$  is equivalent to  $\frac{a+3x}{c} \times \frac{2bx}{9a}$ , or to  $\frac{2abxx+6bx^3}{9ac}$ .

If say all these are evident, because it will appear at first sight, that the proposed quantities are produced, by multiplying the roots into themselves (as  $aa$  from  $a$  into  $a$ ;  $aacc$  from  $ac$  into  $ac$ ;  $9aacc$  from  $3ac$  into  $3ac$ , &c.) The rule is to extract the required root of the numeral coefficient, if there be any, and to divide the exponents of the literal or algebraic quantities by the number that denominates the root required. It is evident from the application of this rule, that any power which has a positive sign may have either a positive or negative root, if the root is denominated by an even number, because  $+$  or  $-$ , multiplied into themselves an even number of times will give  $+$ . Also, that if a power have a negative sign, no root of it denominated by an even number can be assigned. But if the root to be extracted is denominated by an odd number, the sign of the root will be the same as the sign of the given quantity whose root is required. However, it will often happen, that the number, denominating the required root, will not exactly divide the exponent of the given power, in which case the required root will have a fractional exponent, thus,  $\sqrt[3]{8a} = 2a^{\frac{2}{3}}$ . But when quantities consist of several terms, the business is performed as in numbers.

Thus, to extract the square root out of  $aa + 2ab + bb$ ; in the first place, write the root of the first term  $a$ , viz.  $a$ ; in the quotient; and having subtracted its square  $a \times a$ , there will remain  $2ab + bb$  to find the remainder of the root by. Say, therefore, how many times is the double of the quotient, or  $2a$ , contained in the first term of the remainder  $2ab$ ? I answer,  $b$  [times]; therefore write  $b$  in the quotient, and having subtracted the product of  $b$  into  $2a + b$ , or  $2ab + bb$ , there

aa + 2ab + bb (a + b  
aa  
—  
0 + 2ab + bb  
+ 2ab + bb  
—  
0 0

this divided by  $3a^2$  will give  $-\frac{x^6}{9a^3}$  for the next term of the quotient, &c. But the roots of quantities of this kind are much more expeditiously obtained by means of the binomial theorem. For the square root of  $a^2 + x^2 = a^2 + x^2)^{\frac{1}{2}}$ ; and  $a^2 + x^2)^{\frac{1}{2}} = a^2)^{\frac{1}{2}} + \frac{1}{2} \times a^2)^{\frac{1}{2}-1} \times x^2 + \frac{1}{2} \times \frac{\frac{1}{2}-1}{2} \times a^2)^{\frac{1}{2}-2} \times x^2)^2 + \frac{1}{2} \times \frac{\frac{1}{2}-1}{2} \times \frac{\frac{1}{2}-2}{3} \times a^2)^{\frac{1}{2}-2} \times x^2)^3, &c. = a^2)^{\frac{1}{2}} + \frac{1}{2} \times a^2)^{-\frac{1}{2}} x^2 + \frac{1}{2} \times -\frac{1}{4} \times a^2)^{-\frac{3}{2}} x^4 + \frac{1}{2} \times -\frac{1}{4} \times -\frac{1}{2} \times a^2)^{-\frac{5}{2}} x^6, &c. = a + \frac{1}{2} \times a^{-1} x^2 - \frac{1}{8} \times a^{-3} x^4 + \frac{1}{16} \times a^{-5} x^6, &c. = (bringing the powers of a from the numerators to the denominators, by changing the signs of their exponents)  $a + \frac{x^2}{2a} - \frac{x^4}{8a^3} + \frac{x^6}{16a^5}, &c.$$

Thus also the cube root of  $a^3 + x^3 = a^3 + x^3)^{\frac{1}{3}}$ ; and  $a^3 + x^3)^{\frac{1}{3}} = a^3)^{\frac{1}{3}} + \frac{1}{3} \times a^3)^{\frac{1}{3}-1} \times x^3 + \frac{1}{3} \times \frac{\frac{1}{3}-1}{2} \times a^3)^{\frac{1}{3}-2} \times x^3)^2 + \frac{1}{3} \times \frac{\frac{1}{3}-1}{2} \times \frac{\frac{1}{3}-2}{3} \times a^3)^{\frac{1}{3}-3} \times x^3)^3, &c. = a^3)^{\frac{1}{3}} + \frac{1}{3} \times a^3)^{-\frac{2}{3}} x^3 + \frac{1}{3} \times -\frac{1}{3} \times a^3)^{-\frac{5}{3}} x^6 + \frac{1}{3} \times -\frac{1}{3} \times -\frac{2}{3} \times a^3)^{-\frac{8}{3}} x^9, &c. = a + \frac{1}{3} \times a^{-2} x^3 - \frac{2}{9} \times a^3 \times x^6 + \frac{5}{81} a^{-8} x^9, &c. = a + \frac{x^3}{3a^2} - \frac{x^6}{9a^5} + \frac{5x^9}{81a^8}, &c. See Maclaurin's Algebra, part i. ch. viii. p. 50, 51. See Root.$

**EXTRACTOR**, in *Midwifery*, an instrument contrived to extract children in cases of difficult births. We have the description of a forceps for extracting children by the head when lodged low in the pelvis of the mother, in the *Medic. Ess. Edinb.* vol. iii. art. 20. See also the abridgment of this book, vol. ii. p. 438, where some alteration is mentioned of this instrument from Giffard's *Midwifery*, and an improvement of it by Mr. Freke. See **FORCEPS**.

**EXTRACTUM CATHARTICUM**, a form of medicine in the London Dispensatory, intended as an equivalent for the *extractum Rudii*, commonly called Rudius's pill, and which is for many reasons a better composition than that pill. It is now called "extractum colocynthidis compositum." See **COLOCYNTHIS**.

**EXTRADOS**, the outside of a vault.

**EXTRANEOUS FOSSILS**, in *Geology*. Adventitious, secondary, or figured fossils, have among them (*see FOSSILS, Extraneous*) those remains and exuvia of organized beings, which are found imbedded in the strata of the earth. Since the discovery of Mr. William Smith, that each particular shell, and other organic remain, has its proper and appropriate place in the lamina of some particular stratum, and of which it is often a perfect, and, perhaps, the most unerring test of identity, in most instances, the knowledge and exact discrimination of these numerous animal and vegetable remains has appeared a matter of the first importance to geologists, especially since it has been further ascertained, as it now is, that most, if not every one, of the organic remains, differ essentially from any recent species of the animals and plants, to which former, and too cursory, observations had referred them; while many of them differ altogether and entirely from any thing now living or growing; which two points ascertained, have tended irresistibly to shew that

these organic remains were not entombed by the Mosaic deluge, as most writers had supposed, because they differ entirely from the antediluvian race, of which the present living ones are the descendants and exact representatives, as the Mosaic account informs us, and are not of subsequent creation. Another result of the former of these facts has been to shew, that the several animals and plants whose fossil remains we meet with in the strata, lived and died on the stratum in which we find them, prior to the deposition, and, perhaps, prior also to the creation of the matter of the lamina which covers them; and that the period of the existence of particular species was in most, if not every instance, limited to that took up in the deposition of the particular stratum in which they are found imbedded, seeming to suggest, that they were *created* at the period of the stratification, which answers to the lowest lamina in which they are found, and ceased to exist altogether at the period answering to the highest lamina in which they are found; a supposition in no ways inconsistent with the Mosaic account of creation, if the whole of the fossil race be different from the present race of organized beings, and of a period of time antecedent to the events described by the sacred historian, except in his introductory words, "In the beginning God created the heavens and the earth." It may, possibly, be urged, against the idea of a temporary duration of the primitive animals and plants, and their becoming after that *extinct*, that the same kind of organic remains are found again, after large successions of depositions with remains of different beings, in ascending the series of strata, or in very distant parts of the globe; to which it may be answered, that where sufficient discrimination has been made in the specific differences of organic remains resembling each other, but found imbedded in a strata separated by those of a different kind, and with different kinds of organic beings in them, it has generally, if not always, turned out, that the remains resembling each other, and hitherto supposed identic, are in reality not so, but of perfectly distinct species, their *varieties*, as some might be disposed to call them, in conformity to the language of the naturalists respecting accidental deviations in some recent species, being *constant*, and such as properly constituted distinct species in the great families of the primitive creation. Respecting organic substances found at very distant places on the globe, which, on being brought together and thoroughly examined, appear to be identic; before any argument is drawn therefrom, against the temporary existence and extinction of their originals in the primitive race which inhabited the waters of this globe, it should be distinctly ascertained that the series of strata and organic remains above and below the two places in the series whence the specimens were brought are really different; or, in other words, that the identic species really do belong to different parts of the series of strata: for if, on the contrary, they belong to the *same stratum*, however its obvious mineralogical character may appear changed, it is to be expected that the organic remains will be identic, since Mr. Smith has, on tracing the ending or actual out-crop of a stratum for several hundred miles, always found the organic remains the same; as the numerous specimens in his collection, marked and brought from the extreme and intermediate points of such examination, do testify.

It is also to be taken into consideration, that the discoveries of Mr. Farey, relative to denudated tracts on our globe, shew the possibility, and, perhaps, the frequent occurrence of such deep excavations being left in the strata of the earth, as to exhibit the edges, and indeed considerable tracts of the planes of strata, at immense depths in the series, below those proper to the general strata on the sur-

face, and having their regular basket, or ending, on the surface, at great distances from such denudated exposures of them. The immense denudation, for instance, which has laid bare the fourth or lowest limestone rock of Derbyshire and Staffordshire, and the excavation of Dove-dale and other vallies therein, appears to have exposed strata to view, which are from  $1\frac{1}{2}$  to 2 miles in perpendicular depth beneath the red earth, or gypseous tract, which surrounds them on all sides! (except, perhaps, a narrow strip on the north, along the grand ridge, or waterhead of the island,) which lower exposed parts of the fourth lime rock do not, perhaps, anywhere basket, or come regularly to the surface, within 90 or 100 miles of Dove-dale and other vallies, where the denudation has exposed them. The continents seem, from the relations of travellers, likely to furnish numerous instances of denudations in the mountain chains, which will be found to expose strata that lie very low indeed in the general series, and at very great distances from the regular or continued line of ending or outcrop of those particular strata; and, without adverting to which circumstances, the exact identity of organic remains from distant places so circumstanced, might seem to contradict our ideas of their being peculiar to peculiar strata. But after all, should identically the same species of organic remains be found in distant parts of the series of terrestrial strata, what have we to limit the architect of "heaven and earth," from having re-created similar animals or plants during the countless periods of the primitive creation and existence? Analogy surely cannot be said to do this, when the animals and plants created since he said "Let the waters be gathered together, and let the *dry land* appear," and which still continue to exist, have so many points of resemblance to some of the primitive and extinct ones, both in forms and habits, that they have for ages passed as identic therewith. Mr. James Parkinson and Mr. W. Martin, having engaged in works intended to collect information on, and more accurately to discriminate, extraneous or organic fossil remains, which works are still in progress, and the results of Mr. W. Smith's labours and those of his pupils being yet in a great measure unpublished, we shall defer what we have further to add on these highly interesting and curious relics to the article *RELICUIA*, which seems, indeed, their more appropriate title. In the mean time, as the usual names of the several fossil animals and plants, &c. occur, we shall not fail to lay before our readers such facts and particulars as we can collect, and with propriety communicate, concerning the objects of the unpublished researches of the meritorious individuals alluded to; to whose credit it ought to be known, that extended and undisguised communications have all along been made among the circle of their friends, and in consequence of which a spirit of enquiry on the subject has been excited, in various districts of the kingdom, from which the happiest consequences to science may be expected shortly to arise.

*EXTRANEONS*, *Extraneus*, Lat. belonging to nothing, forcing. This word, during the last century, was admitted into the musical technica, in speaking of an unusual and irregular change of key, which is called extraneous modulation, or modulating into an unrelative key, as in the key of C natural, D with a sharp  $3d$ , D  $b$ , B  $\sharp$ , and B  $b$ , which are unrelative keys, having no found in common with the chord of C natural. With respect to extraneous modulation, Rousseau says that no composers have frequent recourse to sudden and unusual modulation, but those who are sterile in fancy and invention: and we should believe the assertion well founded, if Eman. Bach, Haydn, and Mozart, were excepted, who cannot be accused of want of invention.

It is to the clumsy imitators of these great masters, who, in total want of melody, have recourse to unexpected harmony, that Rousseau's accusation seems to attach.

*EXTRAORDINARIUM*, in *Roman Antiquity*, a body of forces, consisting of a third part of the horse, and a fifth part of the foot, which was separated from the rest, to prevent any design that might be formed against the natural forces. See *ABLECTI*.

*EXTRAORDINARY*, something out of the common course.

*EXTRAORDINARY couriers*, are those sent express on some urgent occasion.

*EXTRAORDINARY ambassador*, or *envoy*, is such a one as is sent to treat or negotiate some special and important affair, as a marriage, a treaty, confederacy, &c. or even on occasion of some ceremony, as condolence, congratulation, &c. See *EMBASSADOR*.

A gazette, journal, or other news-paper extraordinary, is that published after some great and notable event, containing the detail or particulars thereof, which are not found in the ordinary papers. Our news-writers generally use postscripts, or supplements, instead of extraordinary.

*EXTRAORDINARY culverin*. See *CULVERIN*.

*EXTRAVAGANTES*, a part of the canon law, containing divers constitutions of the popes, not included in the body of the canon-law; whence the denomination *extravagantes*: "quasi extra corpus juris vagantes."

The *extravagantes* are divided into two parts: the first contains twenty constitutions of John XXII. and the second other later constitutions of the said John, and his successors. See *CANON-LAW*, and *DECRETALS*.

*EXTRAVASATION*, a term in *Surgery*, derived from *extra*, *out of*, and *vasa*, *the vessels*; it signifies an effusion of any fluid from the vessels, viscus, or receptacle, in which such fluid is naturally contained, and the passage of the same into another situation, which is very frequently the interstices of the cellular membrane. In the head, blood is often extravasated, under the cranium, upon the surface of the dura mater, in consequence of the rupture of one of the arteries of this membrane from external violence. The same fluid is also frequently extravasated on the pia mater, and in the convolutions of the cerebrum, or more deeply in the ventricles, and very substance of the brain.

In cases of wounds of the abdomen, large quantities of blood are occasionally extravasated in the cavity of the peritonæum, or the contents of the stomach, bowels, gall-bladder, or some other injured viscus, may become effused. When the urinary bladder is wounded, or when a slough takes place in a certain part of it, from the distension occasioned by a long protracted, and unrelieved retention of urine, the latter fluid may become extravasated in the abdomen. In the example of strictures, the urethra occasionally ulcerates between the obstruction, and the neck of the bladder, and the urine is consequently extravasated in the cellular membrane of the perinæum and scrotum. Sometimes, when a portion of the bowels mortifies, after being returned into the belly, in cases of hernia, the intestinal matter escapes from the alimentary canal, through the breach occasioned by the sloughing.

In the thorax, surgeons sometimes have opportunities of seeing cases, in which considerable extravasations of blood arise, in consequence of stabs and gun-shot wounds.

In the limbs, and indeed, we might say, in every situation, practitioners frequently meet with extravasations of blood, in cases of wounded arteries, aneurisms, and violent contusions

## EXTRAVASATION.

contusions and blows, which rupture vessels of important size. Bloody swellings, produced in the last-mentioned manner, are technically named ecchymoses, and have already been treated of elsewhere. See ECCHYMOSES.

Our design, in the present place, is to consider extravasations in a surgical point of view, as they occur in the head, the chest, and the belly; taking occasion, however, to refer the reader for certain parts of the subject to other places in this work.

*Extravasation of blood in the head, from external violence.*—After explaining with equal perspicuity and elegance, how the dura mater serves as a pericorium to the internal surface of the bones of the cranium, in the same manner as the pericranium does to the external table, Mr. Pott notices, that by blows, falls, and other shocks, some of the larger of the vessels, which carry on the communication between the dura mater and the skull, may be broken, and a quantity of blood shed upon the surface of that membrane. This, he observes, is one species of bloody extravasation, and, indeed, the only one which can be formed between the skull and dura mater. If the broken vessels be few, and the quantity of blood which is shed, be small, the symptoms are generally slight, and, by proper treatment, disappear: when they are large, or numerous, or the quantity of extravasated fluid considerable, the symptoms are generally urgent in proportion; but, continues Mr. Pott, whether they be slight, or considerable, whether immediately alarming, or not, they are always, and uniformly, such as indicate pressure made on the brain and nerves, *viz.* stupidity, drowsiness, diminution, or loss of sense, speech, and voluntary motion.

The shock which the head sometimes receives by falls from on high, or by strokes from ponderous bodies, may likewise occasion a breach in some of the vessels, either of the pia mater, or brain, and thus produce an extravasation of the fluid which should circulate through them.

Mr. Pott remarks, that an extravasation may be the only complaint caused by the accident; or it may be joined with, or added to, a fracture of the skull. But, this is not all; for it may be produced not only when the cranium is unhurt by the blow, but, even when no violence of any kind has been offered to, or received by the head.

Vertigo, vomiting, stupidity, hemorrhage, loss of sense and motion, either partial or total, are set down by this celebrated surgical author as the symptoms of an extravasation within the cranium; sometimes one or more occur in the same subject; sometimes all of them. These symptoms, which are all easily accountable for from extravasation of fluid, and unnatural pressure made on the brain and nerves, are, says Pott, frequently mistaken as indications of a disease, which, considered abstractedly, can never cause them; he means a simple undepressed fracture of the cranium, which may be accompanied by them, but cannot cause them.

The same writer repeats, that when a fluid is extravasated in any considerable quantity within the cavity of the cranium, if any bad symptoms are produced by it at all, they are, and must be, such as indicate pressure made on the brain, and origin of the nerves, occasioning thereby either disturbance, or abolition of the offices of sense and motion; and this in a different degree, according to the quantity, kind, and situation of the pressing fluid.

Mr. Pott seems to have entertained the common notion of hemorrhage from the ears and nose being also symptoms of an extravasation. However, the least reflection must soon make any body perceive, that a bleeding from those parts is only indicative of their having sustained a violent shock

in common with the rest of the head. Even the degree of violence is not at all denoted with any certainty by these circumstances; for, with respect to the nose, we know, that, in many persons, the slightest cause will make it bleed.

When the above-mentioned symptoms exist, Mr. Pott was of opinion, that we might pronounce, in a positive manner, our judgment, that the brain suffers compression; but, says he, to our very frequent mortification, we find these are the only circumstances which, in such case, we can depend upon; every thing else which relates, or belongs to them, being involved in a most perplexing obscurity. We not only have no certain infallible rule whereby to distinguish what the pressing fluid is, or where it is situated; but we are, in many instances, absolutely incapable of knowing whether the symptoms be occasioned by any fluid at all; for, a fragment of bone broken off from the internal table of the cranium, and making an equal degree of pressure, will produce exactly the same complaints.

When a case, attended with the preceding symptoms, occurred, the old surgeons used in general to conclude, that the brain had suffered a concussion, to which all the consequences were imputed.

Mr. Pott observes, that a concussion and an extravasation are very distinct causes of mischief, though not always very distinguishable. M. Le Dran, and others of the modern French writers, have made a very sensible and just distinction between that kind and degree of loss of sense, which arises from a mere commotion of the brain, and that which is caused by a mere extravasation, in those instances, in which the time of the attack or appearance of such symptoms, is different, or distinct. The loss of sense, which immediately follows the violence, say they, is most probably owing to a commotion; but, that which comes on after an interval of time is past, is most probably caused by extravasation.

Mr. Pott remarks, that this distinction is certainly just and good, as far as it will go. That degree of abolition, or diminution of sense, which immediately attends, or follows the blow or fall, and goes off again, without the assistance of art, is in all probability occasioned by the sudden shake or temporary derangement of the contents of the head; and the same kind of symptoms recurring again some time after they had ceased, or not coming on until some time has passed from the receipt of the violence, do most probably proceed from the breach of a vessel within, or upon the brain. But, unluckily, we have it not very often in our power to make this exact distinction. An extravasation is often made so immediately, and so largely, at the instant of the accident, that all sense and motion are instantaneously lost, and never again return. And it also sometimes happens (continues Mr. Pott), that, although an extravasation may possibly not have been made at the moment of the accident, and the first complaints may have been owing to commotion merely, yet a quantity of fluid having been shed from its proper vessels very soon after the accident, and producing its proper symptoms, before those caused by the commotion have had time to go off, the similarity of the effects of each of these different causes is such, as to deprive us of all power of distinguishing between the one and the other, or of determining, with any tolerable precision, to which of them such symptoms as remain are really owing.

Mr. Pott next observes, that the nature and degree of the symptoms, produced by the pressure of an extravasation, are various and different in different persons, according to the kind, quantity, and situation of the pressing fluid. Sometimes it is mere fluid blood; sometimes blood in

## EXTRAVASATION.

a state of coagulation; sometimes it is a clear lymph; and, at others, blood and water are found mixed together; each of these is found either simple or mixed in different situations; that is, between the skull and dura mater, between the dura and pia mater, or in the natural cavities of the brain, called its ventricles, and sometimes, in cases of great violence, they are found at the same time in all these different parts. Sometimes, a considerable quantity is shed instantly at the time of the accident; and sometimes the breach, by which the effusion is made, is so circumstanced, both as to nature and situation, that it is at first very small, and increases by faster or slower degrees. In the former (says Pott), the symptoms are generally immediate and urgent, and the extravasation is of the bloody kind. In the latter, they are frequently slight at first, appear after some little interval of time, increase gradually, till they become urgent, or fatal, and are, in such case, generally occasioned by extravasated lymph. So that although the immediate appearance of bad symptoms does most certainly imply mischief of some kind or other, yet, on the other hand, no man ought to suppose his patient free from hazard, either because such symptoms do not shew themselves at first, or because they appear to be but slight; those which come on late, or, appearing slight at first, increase gradually, being full as much to be dreaded as to consequence as the more immediately alarming ones; with this material difference between them, that the one may be the consequence of a mere concussion of the brain, and may by means of quietude and evacuation go quite off; whereas, the other being most frequently owing to an extravasation of lymph, (though sometimes of blood also,) within the substance of the brain, are very seldom removed by art. (Pott's Works, vol. i.) It appears from some excellent observations published by Mr. Abernethy on the subject of injuries of the head, that a fracture of the skull is not likely to be followed by an equal degree of extravasation in every part, as the vessels, connecting the dura mater to the cranium, are in most parts of that membrane of a small size. If these are accidentally ruptured, a slight hemorrhage ensues, which soon stops, and only a thin stratum of coagulated blood is found, if the bone be removed. But, says Mr. Abernethy, if the fracture happens in the track of the principal artery of the dura mater; if the trunk, or even a considerable branch of that vessel be torn, the hemorrhage will be profuse, and the operation of the trephine becomes immediately necessary to preserve the life of the patient.

When an interval of sense occurs between the blow and the stupor occasioned by the effused blood, the discrimination of the nature of the case is greatly facilitated by that circumstance, as we have already related, because it becomes manifest, that the bad symptoms, which now come on, are not owing to the first mere shock of the external violence on the brain. The patient was most probably stunned by the blow, at the very instant of its occurrence; but he gradually regained his senses, in proportion as the first effects of the shock on the brain subsided. However, as some vessel was wounded by the same blow, an hemorrhage continues under the cranium, on, or within, the brain, and as soon as a certain quantity of blood is extravasated, its pressure produces a recurrence of stupefaction.

Unfortunately, great obscurity attends numerous cases, in consequence of patients having no interval of sense, and remaining in a state of complete stupefaction ever after the accident. We know not, whether the brain is labouring under concussion, or compression, or both; and even when we do know that the bad symptoms arise from an extravasa-

tion, we are frequently unable to say where the effused blood is situated. Now, since the operation of trepanning is not likely to afford assistance, unless the blood be upon the dura mater, so as to allow of being taken away, and since the operation itself is by no means free from danger, we should be very reluctant to put it in practice, without having good foundation for believing that there will be found immediately under the perforation, which we are about to make in the bone, the extravasated blood, which gives rise to the urgent complaints. Practitioners are highly indebted to Mr. Abernethy for a suggestion, which promises to be of exceedingly great assistance in directing whether the trephine ought to be used, or not, on a particular part of the head. "Unless one of the large arteries of the dura mater be wounded, (says this gentleman,) the quantity of blood poured out will be inconsiderable; and the slight compression of the brain, which this occasions, may not be attended with any peculiar symptoms; or, perhaps, it may occasion some stupor, or excite an irritation disposing the subjacent parts to become inflamed; but both these effects will gradually abate, nor will any inflammation ensue, if proper means are taken to prevent it. It is indeed highly probable that in many cases, which have done well without an operation, such an extravasation has existed. But, if there be so much blood on the dura mater as materially to derange the functions of the brain, the bone, to a certain extent, will no longer receive blood from within; and by the operation performed for its exposure, the pericranium must have been separated from its outside. I believe, that a bone so circumstanced will not be found to bleed; and I am certain it cannot with the same freedom and celerity, as it does when the dura mater remains connected with it internally."

In some cases, related by Mr. Abernethy, there was not the least hemorrhage, and this gentleman mentions his having twice been able, by attending to the want of hemorrhage from the outside of the cranium, to ascertain the extent to which the dura mater was detached within. Also, when symptoms seemed to require the perforation of the skull, Mr. Abernethy has frequently seen the operation contra-indicated by the hemorrhage from the bone, and rightly, as the event proved.

When the bone has been for some time bare, this criterion may not be so clear; but Mr. Abernethy scraped the surface of a portion of the skull, which had remained some time in a denuded state, and he found that it bled freely enough to denote that the dura mater was adherent to the inner table, and, consequently, that making a perforation there could be of no service. See *Essay on Injuries of the Head*, p. 32—34.

We shall next enumerate the symptoms of pressure on the brain, and contrast them with those of concussion. It is to be understood, that the complaints produced are nearly the same, whether the pressure is made by an extravasation, or a fracture of the cranium with depression.

### *Symptoms of Pressure.*

1. Patient at first stunned, with cold extremities.
2. Revives, and has an interval of sense, in cases of extravasation, but not in those of a depressed fracture.
3. The quantity of effused blood increasing, he becomes drowsy and stupid.
4. Pulse regular and slow.
5. Patient quite insensible.
6. Pupil dilated.
7. Stertorous respiration.

N.B. When the bleeding is very copious in the first instance,

## EXTRAVASATION.

ance, or when a violent concussion of the brain has also happened, the patient has no interval of sense.

### *Symptoms of Concussion.*

We shall not expatiate on this subject; but refer to COMPRESSION, CONCUSSION, INJURIES of the HEAD, and TREPANNING, for further information.

*Extravasation of blood in the thorax.*—In cases of wounds which penetrate the cavity of the chest, the intercostal arteries are liable to be injured, and if the blood cannot readily flow outward through the wound, it is apt to insinuate itself between the pleura and lungs. An extravasation of blood may also occur in the thorax, when some of the vessels of the lungs, one of the coronary arteries of the heart, or the internal mammary artery, have been wounded. An effusion of blood in the chest may likely obviously originate from a wound of the auricles, or ventricles of the heart, or of the thoracic aorta, and vena cava; but we need hardly observe, that in these and other instances, in which the bleeding would be in a moment excessively profuse, the extravasation proves instantly fatal. Smaller vessels are frequently injured, and pour out a considerable quantity of blood in the chest; yet the records of surgery evince, that these accidents do not always have a fatal termination.

The symptoms commonly enumerated by surgical writers, as indicative of an extravasation of blood in the thorax, are the following: the patient is greatly oppressed, and experiences a kind of uneasiness which will not let him remain for any length of time in the same posture. He feels considerable difficulty in sitting up in bed, except his body be bent a good way forward, in which position the diaphragm is relaxed, and not so much dragged by the weight of the extravasated fluid. When the thighs are bent, the patient can lie with tolerable ease on his back, he is also not averse to lying on the side on which the wound is situated; but he cannot place himself on the opposite one, without feeling very acute pain in the situation of the mediastinum.

His respiration is short, frequent, and interrupted by sighs; his veins become empty, a mortal paleness spreads over his countenance; his extremities become cold; a viscid perspiration covers his neck and temples; his teeth chatter,

his pulse grows weak, and if (as most frequently happens) the lungs are wounded, he coughs up frothy blood, and air issues from the wound.

The preceding class of symptoms, however, are not always attendant on every considerable effusion of blood in the thorax. Wounded persons have been known to die of such an extravasation, whose respiration was tolerably free, and who did not complain of suffering more inconvenience in one posture than another. Sabatier states, that several facts of this kind have fallen under his own observation. Other wounded persons also, who have had most of the complaints, usually imputed to extravasations of blood in the thorax, have been cured by ordinary means.

The symptoms of an extravasation of blood in the thorax are upon the whole very equivocal. Hence; several attentive practitioners have taken extraordinary pains to discover additional circumstances, by which the nature of the case might be more infallibly ascertained. These endeavours, however, seem to have been attended with little success. A surgeon of the name of Valentine asserted, that a sort of ecchymosis of the integuments, over the angles of the ribs, was an invariable symptom; but succeeding observers have not found the remark correct.

When there is no doubt in the practitioner's mind that blood is extravasated in the cavity of the thorax, and that it is the occasion of a dangerous oppression of the lungs and diaphragm, the obvious indication is to endeavour to promote the escape of the effused fluid. However, before undertaking any operation, the revived state of the pulse, the return of warmth in the extremities, and the cessation of convulsions ought to denote, that the hemorrhage no longer continues from the wounded vessels. If vent were given to the extravasation before the bleeding had ceased, a fresh quantity of blood would soon be poured out in the chest, and the patient die exhausted.

For another reason, also, prudence requires that the practitioner should not precipitately have recourse to an operation: *viz.* allowing a little while gives nature an opportunity of employing her own resources, and any one who will be at the trouble of referring to books of surgical cases, will soon meet with examples in which there is every reason to believe that there was more or less blood extravasated in the chest, though the patients completely recovered without any operation.

There are five principal methods of discharging blood from the cavity of the chest. 1. By placing the patient in a posture which favours the escape of the blood. 2. By introducing a syringe for the purpose of sucking it out, or a mere cannula, through which it is to flow. 3. By enlarging the wound. 4. By employing injections, with which the clots of blood are to be washed away. 5. By making an opening into the thorax in a depending situation.

Having thus cursorily treated of extravasations in the chest, we shall quit the subject for the present, intending to resume the consideration of it in speaking of wounds of the thorax. See WOUNDS.

For an explanation of the method of making a depending opening into the chest, see PARACENTESIS.

*Extravasations in the Abdomen.*—Various kinds of fluids may be extravasated in the abdomen in cases of wounds, sloughing of the intestines, &c. Bile, chyle, urine, blood, feces, &c. are all apt to be effused under particular circumstances. Surgeons used formerly to suppose, that whenever any fluid escaped from a vessel, or bowel, into the general cavity of the peritonæum, it always became extensively diffused among the convolutions of the intestines. The erroneous supposition seemed to be con-

## EXTRAVASATION.

formed by facts, the most open to observation, and completely exempt from the possibility of mistake. Practitioners saw that the water of dropsies, the pus of abscesses, which had burst into the abdomen, as well as the chyle and feces, which had escaped through a wound, or other sort of breach of an intestine, were invariably and universally diffused among the folds of the mesentery and bowels after death.

M. Petit (the son) first questioned the accuracy of the foregoing opinion, in relation to the patient while alive. He suggested that as in the living body the intestines were distended with feces, alimentary matter and air, while they were also mutually acting against each other, and in a continual state of compression from the alternate contraction of the diaphragm and abdominal muscles, there might be a superior resistance made to the weight of the extravasated fluid tending to separate the viscera to which we allude. On the contrary, says Petit, is it not possible that, as soon as the patient is dead, and the above kind of resistance is taken away, the extravasated fluid may insinuate itself any where without difficulty? M. Petit remarks, that the truth of the preceding suggestion cannot be doubted, when we consider, that certain cases of hernia get well, notwithstanding the bursting of the gangrenous part of the intestine, after its reduction into the abdomen. In such instances, in fact, the contents of the bowels appear to escape outward through the wound entirely in consequence of the resistance made to their diffusion among the convolutions of the intestines. However it might be objected, that, in cases of hernia, since the bowel is almost always adherent to the edge of the abdominal ring, the issue of the intestinal matter through the wound is rather to be ascribed to the ease with which this event may happen, than to any resistance made internally by the surrounding viscera. But M. Petit cites several cases, which fully confirm, that there is a vast resistance made to the lodgment of extravasated fluids among the convolutions of the bowels, and folds of the mesentery.

After death, any fluid, extravasated in the abdomen, may by its mere gravity insinuate itself any where, and become dispersed among the various parts, because these parts being without action make no opposition. But in the living state, all the abdominal viscera reciprocally act upon each other, and forming, as it were, only one body, by reason of such mutual support, the resistance which is made to any extravasated matter will always keep it from becoming widely diffused, in the manner which many have imagined.

Let us next, with M. Petit, reflect upon the inferences to be drawn from such reciprocal action of the abdominal viscera.

The first consequence is, that an extravasated fluid can only insinuate itself into the cavity of the abdomen, in the same way that a fluid becomes effused in an external part; that is to say, the extravasation can only spread by degrees, and successively, into such places as offer the least resistance. Blood, when it insinuates itself into the interstices of the muscles, can only get from one membranous cell into another, by the first one being so distended, that the fluid can more readily get into a second cell, and from this into a third, than increase the distended state of its first situation. Just so in the abdomen, the blood which escapes from a wounded vessel, is first effused into a situation near the opening in the vessel, either between the peritonæum and surface formed by the intestines, or more deeply among the convolutions of the bowels, or some of the folds of the mesentery. In the proportion as the bleeding continues, the blood forces its original boundary, and dilates the place which it occupies, in every direction, until it meets with less resistance in making its way, either upward or downward, or to the

right or left. The extravasation continues to dilate the new space, which it fills in the same way, until either the first limits are forced, or the effused fluid spreads in some other direction. The extravasation will expand in this manner, till the resistance, made by the viscera, becomes equal to the impetus, with which the blood issues from the vessel. M. Petit was of opinion, that it was this kind of resistance which put a stop to the hemorrhage, even before any coagulum had been formed in the opening of the vessel. That the blood, while flowing from the vessel and in a fluid state, should only make one mass and be contained in one cavity, till coagulation takes place, is a circumstance which cannot rationally be imputed to any thing else, than the resistance depending upon the mutual action of the viscera in the living state. It is also equally certain, that it is in consequence of the sudden cessation of such resistance, that extravasated blood, which is fluid after death, becomes dispersed among the different convolutions of the bowels, and forms numerous scattered collections.

The second inference which M. Petit mentions, as deducible from the resistance arising from the reciprocal pressure of the abdominal viscera, is that an extravasation in the cavity of the abdomen cannot so easily happen, as some have fancied. It was once not an uncommon idea, that a breach in a very moderate vessel could occasion a considerable extravasation, because the orifice could not be compressed, like that of a vessel in a more external situation. It is indeed true, that no compression can be directly applied to the opening in an internal vessel; but the resistance which the surrounding viscera make to the extravasation, operates as a substitute. It is even probable, according to Petit, that when blood is effused in the abdomen, it has a greater resistance to overcome, than when extravasated in an external part. This author states, that the resistance of the cellular membrane, the common bond of connection between the muscles, is undoubtedly less than that which depends on the reciprocal action of the intestines, and rest of the viscera. The incessant alternate motion of the abdomen and thorax is in favour of the preceding opinion. The facility also, with which abscesses situated in the abdomen are discharged, through a small, and very frequently not a depending opening, is an additional fact, proving that the abdominal viscera, by the manner in which they mutually press upon each other, make a greater resistance to an extravasation, than can be made by the cellular substance in other parts of the body.

Swords have often been thrust completely through the body, without giving rise to any dangerous symptoms, or only to such as frequently attend wounds, which do reach into the cavity of the belly. We cannot imagine, contrary to all probability, that, in this case, the weapon has slipped over the intestines, through their interstices, and by good luck has wounded none of the blood-vessels. We must rather conclude, that an extravasation does not always ensue from a wound of the viscera or blood-vessels, or at least, that the extravasation is not invariably attended with such consequences as former practitioners used to suppose.

For the purpose of rendering the foregoing remarks more intelligible, let us follow M. Petit in his observations, and take notice of the principle which he has laid down in his excellent memoir, *viz.* that without a particular action in the muscular fibres of the intestine or artery, no extravasation would occur in the abdomen, even were there a breach in such bowel or vessel. Supposing the blood vessels destitute of action, and the place of the opening pressed upon by a force equal to that, which operates upon the rest of their extent, the fluid, which they contain, would never

## EXTRAVASATION.

be effused in the abdomen, so as to form an extravasation. Besides its being evident, that this must be the fact, M. Petit mentions his having actually observed it in the body of a man, who died of gangrene in the abdomen, in consequence of a hernia, which was attended for upwards of a fortnight with the most violent symptoms of strangulation. Nearly the whole of the intestinal canal was equally affected with gangrenous mischief, so that it was scarcely possible to handle any of the bowels without occasioning a breach in them. However, although the intestines were filled with very fluid excrement, none of it was extravasated in the abdomen. In several places, indeed, Petit discovered numerous little breaches of continuity, which had allowed a little of the excrement to escape, but only just enough to tinge the adjacent parts. Petit acknowledges, at the same time, that round where these holes were situated, some slight adhesions had taken place between the bowels, and these and other parts; but they were so weak, and easily broken, as to be quite incapable of hindering an extravasation. Petit concludes, that in this instance no extravasation happened, because the intestinal canal was every where affected with gangrene in nearly the same degree, and the disease had destroyed the tone and action of the muscular fibres of the intestines.

It is contended by Petit, that the foregoing case affords sufficient proof, that, without a contractile power in the blood vessels and intestines, no extravasation of their contents could be produced in the abdomen, and that such an event would certainly be opposed by the action of the abdominal muscles and diaphragm, which make uniform and equal pressure upon all the viscera. If this statement be correct, it is obvious, first, that the greater the action of the wounded vessels is, in relation to the quantity of fluid which they have to propel, the greater will be an extravasation from them: secondly, that no extravasation can arise unless the action of the vessels themselves be capable of overcoming the resistance depending upon the mutual action of the parts. Hence, only wounds of vessels above a certain size can give rise to extravasations; at least, to any of importance. The veins cannot occasion so much extravasation as the arteries: nor are wounds of the intestines so apt to be followed by an effusion of the chyle and feces, as the same injuries of the blood vessels are liable to be attended with an extravasation of blood. Petit was also of opinion, that wounds of the stomach were not so often as those of the bowels the cause of this kind of accident.

The feces cannot be so easily extravasated as blood, not only because the action of the intestines, particularly that of the small ones, upon their contents, is weaker than that of the blood vessels upon the blood, but, principally, because, when there is a breach in one of the bowels, the contents will continue their course through the intestinal canal, without any need of there being a considerable obstacle to the occurrence of an effusion. However, Petit admonishes us not to conclude, from what has been said, that the chyle and feces can never be extravasated in the abdomen. There is no doubt whatever, he observes, that an extravasation may take place, when the wound in the bowel is of ample size, the gut filled with chyle or excrement, and care is not taken to empty the large intestines very often with glysters. The event may also happen, when pain and irritation render the muscular action of the intestines violent, irregular, and convulsive, and when unequal pressure is made upon the abdomen. Under such circumstances, the resistance made to an extravasation, by the reciprocal action of the viscera, is overcome, and the contents of the bowels will continue to be effused, until the impulse arising from the contractile power

of these organs returns to a state of equilibrium with the resistance depending on the mutual action of all the viscera.

The extravasation of chyle and feces does not take place differently from that of blood; but in wounds of the bowels there is this advantage, that the same opening which has given passage to the extravasated fluid, may also allow it to return and pass off. Petit remarks that we need no further proof of what has been stated, than the great evacuations of blood, which some wounded persons have had with their stools, without being afflicted with any of the symptoms of extravasation. It is highly improbable, that such bleeding could depend upon the injury of any of the vessels ramifying upon the intestinal canal, since their size is too inconsiderable. We rather believe that, in these cases, some vessels, either of the mesentery, or some other part, have been wounded at the same time as the intestine, and that the blood has insinuated itself into, and taken its course through the bowels, in consequence of the resistance made to its extravasation among the viscera.

The foregoing remarks, made by Petit (the son), clearly prove not only that an extravasation of feces cannot so easily happen in the abdomen as has been imagined; but, also, that it is less dangerous than an effusion of blood usually is, and that it is accompanied by less violent symptoms. When the contents of the bowels are extravasated, adhesions are likewise observed to form more readily, and to limit the effused matter sooner, than when the extravasation consists of blood. After such adhesions have once formed, it is probable that the extravasated matter may be got rid of in the same favourable way, as certain abscesses, which have discharged themselves into the intestinal canal. Blood, however, cannot insinuate itself again into the canal of the vessel, out of which it has escaped, because a clot blocks up the opening. But a wound in an intestine remains continually open, till it is closed by the adhesions which the bowel contracts to the adjacent parts: adhesion, indeed, is the only means by which a wound of this description can be healed.

M. Petit remarks, that among the numerous facts which might be adduced in proof of the difficulty with which a wound of the stomach permits the aliment to be extravasated, the operation of an emetic in this case is a striking one. Petit expresses his belief, that vomiting does not depend upon the action of the muscular fibres of the stomach, but entirely upon the sudden and violent contraction of the abdominal muscles. This author conceives, that, if the particular action of the stomach itself had much concern in the production of vomiting, an extravasation of the alimentary matter would necessarily happen in the abdomen when that viscus is wounded. However, in the instances referred to by Petit, the occurrence did not take place, because, notwithstanding the violence with which the abdominal muscles and diaphragm contracted, they made equal and uniform pressure on all sides of the stomach. The danger of an extravasation is also less, inasmuch as a wound of the stomach is always much smaller in relation to its cavity, than that of a bowel, in regard to the intestinal canal.

Circumstances are very different, in respect to wounds of the gall and urinary bladders, especially when these receptacles are full. An extravasation is then an inevitable consequence, both on account of the great fluidity of the bile and urine, and of the contractile power with which the parts are endued, and against which the action of the abdominal muscles makes no sort of resistance. An extravasation of these fluids is extremely dangerous, by reason of their irritating quality with respect to the viscera. The colics,

tics and irregular contractions which such stimulating fluids excite, cause the extravasation to become more widely diffused. The ease also, with which the bile and urine mix with the serum, that naturally moistens the surfaces of all the viscera, leads us to suspect, that whenever those fluids are extravasated, they very soon become universally dispersed among all the convolutions of the intestines.

Against these latter extravasations little can be done, and unless they are in small quantity, and their increase can be prevented, the patient's life hardly admits of being saved. Leaving a catheter in the bladder, indeed, is a sure means of hindering the extravasation of urine from augmenting; but not much confidence can be placed in the kind of outlet afforded by the duct of the gall-bladder.

When the extravasated matter is completely encysted and circumscribed, it happens, that as such matter had to overcome the resistance of the parts before it could be effused, no sooner is a passage afforded for its escape, than the reaction of the separated parts necessarily forces out whatever fluid has insinuated itself between them. This is a third consequence, which is pointed out by Petit as resulting from the resistance, made by the reciprocal action of the abdominal viscera, to extravasations.

The foregoing observations tend to shew, that an extravasation in the abdomen, and especially one of blood, may be as completely discharged as a collection of fluid in the thorax. The evacuation, at least, may always be easily effected, when the extravasation is bounded at any part by the parietes of the abdomen: a circumstance, which must invariably occur, whenever the extravasation is considerable. Indeed Petit informs us, that it was always the case, as far as his experience went even when the effusion was not very copious.

It is not enough to make surgeons understand, that fluids, extravasated in the abdomen, admit of being discharged by an operation; we deem it also necessary to explain the symptoms denoting the cases in which such a proceeding is proper.

In order to understand this interesting part of the subject, Petit, and most surgical writers after him, have advised us to draw a distinction between the consecutive symptoms and the primary ones, or those which attend the wound from the first, and are, strictly speaking, proper to it, because they depend essentially upon the division of the injured parts. Such breach of continuity occasions, from the first, pain, irritation, tension, convulsions, and swelling and inflammation of the abdomen, affections naturally leading to other consecutive symptoms, which vary according to the injured parts, and the degree of inflammation. Of the latter class are, hiccough, vomiting, constipation, suppression, or retention of the bile and urine, a great deal of fever generally at first, and, after the inflammation has attained a certain pitch, a concentration and sinking of the pulse, considerable prostration of strength, and cold sweats.

If when the first train of symptoms has been relieved, and after an interval of from four to eight days or more, the symptoms recur, or become exasperated, without any apparent cause, we may infer that such consecutive complaints depend upon an extravasation.

It may at first seem extraordinary, that the symptoms of an extravasation of blood should be consecutive; for, as the effusion takes place at the moment, when the wound first happens, why do not the symptoms commence at the same time?

Petit has referred the reason to the following circumstances: blood, extravasated in the abdomen, does not give rise to any complaints, either by the pressure which it

makes, or by its quality; and whenever any symptoms are occasioned on the first occurrence of the effusion, they are those of weakness, depending on the loss of blood to the circulation. The extravasation afterwards becomes entirely circumscribed by the adhesions, which are produced by the inflammation around. An additional quantity of fluid continues to be secreted from the vessels into the encysted cavity of the effused blood, and consequently pain, inflammation, &c. are occasioned by the increasing distention, now produced.

We shall not stop to enquire into the accuracy of the latter part of the foregoing statement, as the fact, that the symptoms of an extravasation are consecutive, is a piece of information highly important to the practitioner, while the theory of the subject is a subordinate consideration.

The remainder of the remarks, respecting extravasations in the abdomen, and their treatment, will be found in the article WOUNDS. Some observations will also be offered, when we speak of HERNIA.

EXTRAVASATION is a term sometimes likewise used by the gardeners in speaking of gums, juices, &c. which issue out of their trees either spontaneously, or at incisions.

EXTREAM, or EXTREME, is applied to the last and outermost part of any thing; or that which finishes and terminates it on that side.

The extreams of a line are points. There is no passing out of one extream into the other, without going through the middle. Extream remedies must only be had recourse to in extream necessity.

Some anatomists apply the denomination extremes, or extremities, to the arms and legs. See EXTREMITIES.

EXTREAMS, in *Logic*, denote the two extream terms of the conclusion of a syllogism, viz. the predicate and subject.

They are called extreams, from their relation to another term, which is a medium or mean between them.

The predicate, as being likewise had in the first proposition, is called the *major extremum*, greater extream; and the subject, as being put in the second, or minor proposition, is called the *minus extremum*, lesser extream.

Thus, in the syllogism, man is an animal: Peter is a man, therefore Peter is an animal; the word animal is the greater extream, Peter the less extream, and the man the medium. See SYLLOGISM.

EXTREAM and Mean Proportion, in *Geometry*, is when a line is so divided, that the whole line is to the greater segment, as that segment is to the other.

Or, as Euclid expresseth it, when the line is so divided, that the rectangle under the whole line, and the lesser segment, is equal to the square of the greater segment.

The invention of this division is thus: let the given line be  $AB = a$  (*Plate VII. Geometry. fig. 87.*) and for the greater segment put  $x$ , the lesser will be  $a - x$ . Then, by the hypothesis,  $a : x :: x : a - x$ . Therefore,  $a a - a x = x x$ , consequently  $a a = a x + x x$ . And, by adding  $\frac{1}{2} a a$  on each side, to make  $x x + a x + \frac{1}{2} a a$ , a complete square, the equation will stand thus,  $\frac{3}{2} a a = x x + a x + \frac{1}{2} a a$ .

Now, since the latter is exactly a square, its root  $x + \frac{1}{2} a = \sqrt{\frac{3}{2} a a}$ , and by transposition it will be  $\sqrt{\frac{3}{2} a a} - \frac{1}{2} a = x$ ; which last equation is a canon for finding  $x$ .

For at the foot of  $AB = a$ , set at right angles  $CB = \frac{1}{2} a$ ; then draw  $CA$ , the square of which is equal  $AB q + CB q = \frac{3}{2} a a$ . And therefore  $AC = \sqrt{\frac{3}{2} a a}$ ; make  $CD = CA$ . From whence  $CB = \frac{1}{2} a$  being taken as the case

use requires, there remains  $BD = x$ ; which transferred into  $AB$ , shall give the point  $E$ , where  $AB$  is cut according to extremum and mean proportion.

This cannot be exactly done in numbers; but if you would have it tolerably near, add together the square of any number, and the square of its half, and extract, as near as you can, the square root of the sum; from whence taking half, the remainder is the greater part.

EXTREMS, in right-angled spherical trigonometry. When one of the five circular parts of a right-angled spherical triangle, *viz.* the three sides and two oblique angles, (for the right-angle is neglected) is pitched upon for the middle term, then the two circular parts lying immediately next to it are called extremes conjunct; and the two parts remote from the assumed middle part, or not immediately next it, extremes disjunct. See CIRCULAR PARTS, TRIANGLE, and TRIGONOMETRY.

EXTREMUM UNCTION, one of the sacraments of the Romish church, the fifth in order, administered to people dangerously sick, by anointing them with holy oils, and pronouncing several prayers over them.

It is called extremum unctio, as being only given to persons in extremity. In the thirteenth century, it was called the "unction of the sick," and not extremum unctio: for, in the earlier ages, it was given before the viaticum; which practice, according to F. Mabillon, was not changed till the thirteenth century.

The reasons he assigns for the change are, that in that age there arose divers mistaken opinions, several of which we find mentioned and condemned in the English councils; among the rest, it was held, that such as had received this sacrament, in case they recovered, might not make use of their wives, nor eat meat, nor go barefooted; whence they chose to forbear it till the last extremity, which practice prevailed. See the Councils of Worcester and Exeter, in the year 1287; that of Winchester, in 1308; and F. Mabillon, Acta Sancti. Benedicti. Sæc. iii. p. 1.

The form of extremum unctio is now deprecativæ, as the divines call it; formerly it was absolute and indicative. This sacrament is not only in use in the Latin, but also in the Greek church, and throughout the East, though under another name, and with some difference in the circumstances; in that the orientals do not wait till their sick are come to extremity, in order to anoint them; but the sick generally go to church themselves; and it is administered to them as often as they are indisposed: the Greeks taking that direction of St. James, chap. v. ver. 14. which is the foundation of the practice, in a general sense: "Is any sick among you? let him call for the elders of the church, and let them pray over him, anointing him with oil." F. Dandini distinguishes two kinds of unctio among the Maronites: the one called unctio with the oil of the lamp; but this, he suggests, is not the sacramental unctio ordinarily administered to such as are in extreme sickness; because the oil is only consecrated by a priest, and it is given to all who are present; not to the sick only, but also to the healthy; even the priest who officiates partakes of it. The other kind of unctio, according to that father, is only for the sick; this is performed with oil consecrated by the bishop alone, on Holy Thursday; and this, it seems, is the sacramental unctio.

The unctio with lamp-oil is in use, not only among the Maronites, but throughout all the Eastern church, who use it very religiously. The truth is, they do not seem to have any other sacrament of extremum unctio beside this. Yet F. Goar observes, though it be only a ceremony,

with regard to those in health, it is a real sacrament to those that are sick.

In their great churches they have a lamp, wherein this oil for the sick is preserved; this lamp they call *καυθήλα τε ψευδαίων*, that is, *the lamp of oil joined with prayer*; for what the Latins call extremum unctio, the Greeks call *ευχλαίων*, or *αγιον ελαίου*, that is, *oil with prayer, or holy oil*.

EXTREME, in Music, is applied to such intervals as deviate as much as possible from the true chord of the same name, without changing their names; generally when the term extreme is added to the prefix diminished or superfluous (which denote a minor semitone), its effect is to double that diminishing or superfluous effect, or to make it  $\frac{57}{32} \circ = 72 \Sigma + 2f + 6m$ ; but sometimes we find Mr. Orwend applying a major comma and a minor semitone as the effect of his term extreme, or  $\frac{123}{32} \circ = 47 \Sigma + f + 4m$ , = the medius semitone: at other times we find extreme, when added to other prefixes, to have different effects, as extreme sharp intervals, for instance, are sometimes found a minor semitone above the intervals respectively, or  $\frac{34}{32} = 36 \Sigma + f + 3m$ : but in other instances the same prefix signifies a major comma more, or  $\frac{123}{32} \circ = 47 \Sigma + f + 4m$  = the medius semitone. It were much to be wished that these various applications of terms, so perplexing to a reader, could be got rid of, and a consistent nomenclature in harmonies adopted.

EXTREMITIES, in Anatomy, is a term applied to the limbs, as distinguishing them from the other divisions of the animal body, the head, and trunk. They are immediately connected with the latter by one end, and totally free in all other parts. The numerous varieties of their form depend partly on the bones, which enter into their composition; but, in a material degree also, on the soft parts which surround these, and which give to the limbs that roundness and elegance of figure, in which beauty is united with activity and strength. The extremities, being essentially concerned in all the functions of animal life, and constituting the great agents of locomotion, are composed of organs especially destined for these purposes. Their volume is formed by bones and muscles, supplied by numerous vessels, and communicating with the common centre of sensation, the brain, by nerves distributed most extensively; producing, in one part, the most important sense of touch, and giving the spring in all to rapid and varied motions.

The extremities are four in number, divided in man into upper and lower; in other animals into anterior and posterior. Each extremity is divided into four parts; the upper into the shoulder, the arm, the fore-arm, and the hand; the lower into the hip, the thigh, the leg, and the foot. In treating of these, both separately and generally, we shall consider only the bones, and the connections between them. On these depend all the motions of the limbs, the direction and extent of action of the muscles being wholly dependent on the bony points to which they are attached, and on the form and mode of junction of the bones on which they exert their power. The influence of any muscle will be considered in the detailed description of each, and may be easily applied to the subject immediately before us.

Our present plan is to offer, first, some general observations on the external figure of the bones of the extremities, as far as it relates to their uses; on their modes of articulation and their motions. We shall next examine separately and in detail each division of the bones of the upper extremity, the ligaments connecting them, the mechanism of their articulations, and their individual motions; afterwards the combined movements of the several parts, and the powers of the member, as resulting from this construction, both in the

## EXTREMITIES.

passive and active state. A similar mode will be pursued in considering the lower extremity. We shall conclude with a comparison between the upper and lower limbs as to size, figure, direction, motions, and growth.

The bones determine essentially the size, figure, and direction of the extremities, forming, by their assemblage, solid and flexible columns, capable of motion in very varied directions. Some of these in each column differ very widely in form; while others partake of the figure of both opposite varieties. We describe them under the different names of long, of broad or flat, and of short bones.

In the limbs the bones diminish successively in length and size, and increase in number, as we descend from the trunk to the opposite extremity, from the arm, or thigh, to the fingers or toes. In consequence of this arrangement the upper part of the limb enjoys extensive motions, whilst the lower is characterized by multiplied, but confined movements. These bones have every where an analogous structure, being broad and voluminous at their *extremities*, contracted, and frequently rounded in their middle part, or *body*. The increased volume of the extremities possesses the double advantage of enlarging the articular surface, and thereby diminishing the chances of displacement, and of preserving the symmetry of the limb. We perceive, for instance, that the bellies of the muscles correspond to the middle or smallest part of the bone, while the flat and contracted tendons are fixed near the protuberant extremities. The augmentation of size, in the ends of the long bones, is by no means sudden; it commences insensibly from the body. We remark, on these extremities, various eminences, subservient to the purposes of articulation, or giving an advantageous attachment to tendons. The middle part, or body, is generally smooth, offering prominent lines for muscular or tendinous attachments. These, where strongly marked, destroy the cylindrical form of the bone: they are usually three in number, longitudinal, separated by plane surfaces, and give the bone a prismatic figure, as may be observed in the arm, fore-arm, and leg. In these instances a section of the bone is manifestly triangular; yet its internal canal preserves a circular form. We may observe also, that the body, in nearly all the long bones, appears as if twisted on itself; so that the direction of the upper end differs more or less from that of the lower. This is rendered evident, by tracing the oblique course of the prominent lines between the two extremities; for example, in the bone of the arm.

The long bones are formed from three points of ossification. The first of these is observed in the centre of the body, extending on each side to the extremities, at which the bony cylinder is arrived at the period of birth. Soon after this time, a point of bone is perceived in the centre of each cartilaginous extremity, which increases gradually, advancing towards the body, with which it at last unites. From this consideration of the figure and formation of the long bones, we may naturally derive the arbitrary division into a *body* and two *extremities*; which division we shall adopt throughout. The body of the bone is the *diaphysis* of some Latin writers; and the two ends being at first united to the body only by cartilage, are called *epiphyses*.

The broad bones are not found so generally in the extremities as those of the long form; we observe them only at the part immediately united with the trunk, where they offer an ample space for the attachment of the powerful muscles concerned in moving the limb. In our description we observe two *surfaces* and a *circumference*. The former, if they give attachment to muscles, are usually unequal and rough; the latter is thicker than the middle of the bone,

offering more points of origin to muscular fibres, as we may observe in the margin of the hip bone.

The short bones of the extremities are found in situations where it was requisite to unite a certain degree of mobility with firmness, as, for instance, in the foot. They are collected in considerable number in the regions which they occupy; and have numerous eminences and depressions on their external surfaces, necessary for their reciprocal articulations and for the insertion of the connecting ligaments. Nothing can be more irregular than their figure, which, in addition to their comparative smallness and number, has given rise to much ambiguity of description. By considering them under the same aspects as the other bones, and by carefully noticing their relations to these, all confusion may be avoided. The short bones, in general, continue longer in a cartilaginous state than the others, resembling, in the phenomena of their ossification, the epiphyses, or extremities of the long bones.

There still remain some small bones, found only in the extremities, which can hardly be included in either of the above classes, and are distinguished by the epithet of *sesamoid*. They possess this peculiarity, that they are formed, not in common cartilage, but in the middle of a tendon, or ligament, and that no trace of them can be observed in early life. Of their use we shall speak hereafter.

There are some general characters belonging to all the above-mentioned classes of bones. We observe in all eminences and hollows, either giving attachment to muscles, or ligaments, or forming surfaces for articulation. The eminences designed for the former purpose are very numerous in the bones of the extremities, and vary greatly in figure. They sometimes appear only as asperities impressed in the midst of a smooth surface, giving origin to a number of distinct aponeurotic fibres; sometimes as prominences or tubercles more or less elevated and rough, giving insertion to one or more tendons; or, lastly, as a continued raised line. In general these eminences are proportioned to the muscles which are fixed to them; so that under which-ever form they appear, there is an equality of space allowed for the tendinous insertions of muscles of equal bulk. They are in general less strongly marked in the female than in the male; in the infant than in the adult; in feeble animals than in the carnivorous tribes, which live by preying on others. Their prominence is indicative of vigour and activity of motion; being more developed as the muscles are more powerful. This is strikingly exemplified by a comparison of the bones of a well made and muscular man, where the outline of each muscle might be traced with energy and precision through the skin, with those of a weak and ill proportioned male, whose rounded and faintly marked limbs, resembling those of the female, betray a total want of vigour or address. The uses of these eminences may be clearly traced to their removing the insertions of muscles farther from the centre, or axis of the bone, and consequently increasing their power of moving it. The eminences, which give attachment to ligaments, possess the advantage of removing the ligament farther from the joint, and thereby facilitating, and giving greater extent to its motions. These eminences have received different names, according to their situation, their direction, or figure, as we shall see more particularly hereafter.

The hollows observed on the external surfaces of the bones, (with the exception of articular cavities, of which we shall speak below,) are designed either for the attachments of muscles, or for giving passage to their tendons. The first of these have the evident advantage of increasing the surface, without augmenting the bulk of the bone;

## EXTREMITIES.

the latter appear as gutters, or grooves more or less deep, lined by cartilage, and completed by very strong ligamentous bands, through which the tendons glide in their way to their final attachments.

The connections between the bones of the extremities, whatever be their mod., are known by the general term of articulations. Their varieties have given rise to numerous technical, and in some measure obsolete, names, for which we refer to the articles *JOINT* and *DIARTHROSIS*. Some joints allow of motion in every direction; and we may trace a gradual decrease of mobility, through many intermediate steps, till we arrive at articulations which admit only of a gliding of the bones on each other. We have examples of the first in the joints of the shoulder and hip; where the extent of motion requires rounded articular surfaces, concave and convex in the opposite contiguous bones; constituting what is commonly termed the ball and socket joint. In man the moveable bone has the rounded head, the supporting bone the corresponding hollow. In some animals we have instances of a contrary disposition, in which a concavity in the moveable bone moves in all directions on an opposite convex surface. This mode of connection is found only in the shoulder and hip; and one advantage resulting from this structure being found at the upper part of the limbs, is, that the whole member necessarily partakes of the same extensive motions; while it allows of a greater firmness and solidity in the inferior articulations. The joints we have just mentioned are, in this sense, the joints, not only of the bones of the arm and thigh, but of all the limb, the motions of which, considered as a whole, they essentially and principally influence. Hence, if their mobility is destroyed, either by accident or disease, the limb becomes useless: whilst a similar occurrence in the inferior joints produces a partial inconvenience only. By this arrangement also, the joint, which, from its want of firmness, is most liable to injury, is the furthest removed from the immediate action of external bodies.

The extent of motion decreases as we proceed towards the extremities of the limbs. We find no rounded head, whose axis makes an angle with that of the cylinder of the bone, but an articular surface placed directly at the top or bottom. Of this we have examples in the connection of the collar bone with the breast, of the fore-arm with the wrist, &c. In these, all power of rolling the bone, which is enjoyed in a high degree by the thigh, and by the arm, is deficient. In the next step, the motions are confined to flexion and extension, as in the elbow, the knee, and the middle of the fingers. In this division the articular surfaces consist of eminences and hollows adapted reciprocally to each other, allowing of motion in one direction only. They are remarkable also for their large extent, which imparts to them solidity; and for admitting a greater degree of motion in the direction of flexion, than in the opposite one of extension, as may be observed in the knee, elbow, and fingers. The degree of extension is always effectually limited, either by a projection of bone, as in the elbow; or by strong ligaments, as in the knee, &c. In other instances, the articulation allows of rotation only; a convex surface turning in a concave, or a hollow surface rolling over a convex one; both of which may be seen in the motions of the bones of the fore-arm. In the last kind we observe only a gliding of plane articular surfaces on each other, more or less obscure, limited on all sides by ligaments binding the bones closely together. To make up for this very confined motion, we usually find many such joints united, producing in this state a more sensible degree of motion than could possibly occur in any of them singly. This may be seen in the wrist.

In all these articulations we find a smooth and polished crust, of an elastic substance, called cartilage, on the surface of the corresponding bones, the immediate means of their motions on each other. It is supposed to obviate by its elasticity the dangers resulting from sudden and violent shocks. The two corresponding cartilages of opposite bones are so disposed as to touch at all points in some positions of the limb, whilst in others they quit each other more or less, and are found opposite the soft parts surrounding the articulation. They are moulded into the form of the bone to which they adhere, preserving its general figure. But in some cases the cartilage is thicker in its middle than at the edges, thereby increasing the convexity; in others the converse may be observed, and the hollow of the articular surface is proportionably increased. Both occur in the hip and shoulder: the first in the heads of the thigh and arm bones, the last in the cavities which receive them, and in this manner the uniformity of contact is preserved. In the other articulations the cartilaginous crusts are nearly of equal thickness throughout.

The contact of the articular surfaces is secured by ligaments destined immediately for this purpose, and by the muscles which pass from one bone to another, supporting the joint either by the muscular fibres, or their tendons. The ligaments are formed by very strong fibres, a little elastic, disposed in parallel lines, or interlaced in various directions. Their great resistance insures, at all times, more particularly when the limb is at rest, the relations between the opposite bones; their situation limits in a great degree their inordinate motions. We observe them under many forms, and named either from these, or from their situation. Among the first are capsular ligaments, which are found surrounding some of the joints like cylindrical bags, embracing the opposite bones by the circumference of the two ends. Of this we have examples in the hip and shoulder, and nowhere else perhaps in the extremities. The ligamentous fibres are here interwoven and strengthened by the adherence of the surrounding tendons, lost at either extremity in the periosteum, to which they are firmly united. The reason why capsular ligaments are found only in these articulations will be readily understood. They enjoy motion in every way nearly alike, and require on all sides an equal degree of resistance. Where, from the form of the articular surfaces, the motions are confined to narrower bounds, ligaments are necessary only in particular situations in order to regulate them. We find them in the other joints generally on the sides, from which the name of lateral ligaments. These are sometimes rounded, sometimes flat, interwoven with the periosteum at each extremity, formed of fibres lying in parallel lines, or diverging at either end. There are other ligaments, not directly concerned in the joint, which still strengthen and regulate its motions, as may be remarked particularly in the shoulder. Besides these we observe many irregular slips, or bands of ligaments, dispersed here and there over the joint separated by fat and cellular tissue from the neighbouring parts. The ligaments, of whatever description, unite the opposite surfaces of bones, prevent their displacement, and yet allow of easy and rapid motions; a double advantage arising from their firmness on one part, from their flexibility on the other. They sometimes give attachment to muscles.

The muscles surrounding the joints of the extremities are very powerful agents in securing their contact, and the more so as their power increases in proportion as the chance of displacement is greater. The most vigorous efforts at displacement are made during violent and extended motions; at such times the muscles passing from bone to bone, and

## EXTREMITIES.

crossing the articulation, are strongly contracted, are firm in their contractions, and powerfully oppose the tendency which the extremities of the bones may have to abandon each other. In repose, when the muscles are relaxed, and offer but little resistance, the chances of luxation are few, but if they occur, the probability of its taking place is exceedingly increased.

In some joints of the extremities we find a substance of a somewhat cartilaginous structure, occupying the interval between the cartilaginous surfaces, and called for this reason inter-articular cartilage. Such bodies are sometimes moveable, as in the knee, corresponding to the varying want of uniformity in the articular extremities, or fixed more firmly to the end of the bone, or the neighbouring ligaments. They are elastic and highly flexible, resembling cartilage in the first quality, the fibrous ligaments in the second. This peculiarity of structure has given rise to the name of articular fibro-cartilages, a term bestowed on them in recent times by the French anatomist Bichat.

These surfaces are all moistened by a fluid, called synovia, on the composition of which we shall not dwell here. It is secreted by a delicate membrane which completes the structure of the joint, by lining every part of its surface: whatever be the figure of the cartilages, or the ligaments, from both of which it is distinct, it adheres closely to them. It forms a bag without an opening spread over the whole organ, reflected from the cartilages to the ligaments or tendons; so that whatever it embraces is, in reality, without the articular cavity as it is termed, though projecting into it. To the whole it gives that smooth, polished surface so necessary for the easy and rapid movements the articulations enjoy, at the same time secreting the fluid which facilitates them; it gives to the joint also its peculiar shining character.

The most simple motion of articular surfaces, common to them all, is gliding on each other in opposite directions; it is often so obscure as to be scarcely perceptible. As we ascend we find it multiplied in a variety of ways. The limb can be considerably bent, or extended; it can be removed from, or brought nearer to the axis of the trunk: the first of these motions is called abduction, the latter adduction; in some cases, as in the shoulder, they are termed elevation, or depression. The motions of some joints are confined to any two of these, as in the knee; others enjoy the whole, and all the intermediate degrees, as in the thigh. The union of these different movements, as exhibited in the arm or thigh, has been called circumduction. In this case the bone, instead of being moved in one direction, and back again to the opposite, is carried successively through all, describing by its extremity a circle, or the base of a cone, the apex of which is in the articulation above. Rotation, or rolling, is very different from this. In circumduction the bone is moved from its prior situation to a more distant one; in rotation it remains in the same place, it turns only on its axis, as may be observed in simply rolling the arm.

From this cursory review of the external characters of the bones of the extremities, of their modes of connection and motions, we proceed to the detailed description of each. It will be necessary to premise, that in our terms of position and aspect, we shall always suppose the body erect, the arms depending, and the hands supine, so that the little finger is in contact, or at least next to the external side of the thigh. In this situation we shall suppose a vertical plane dividing the body into two halves, from before backward. With a clear impression of this idea we shall find no difficulty or confusion in the terms anterior and posterior, superior and inferior, external and internal, as applied to the different aspects or surfaces of bones; by the latter, internal,

we always mean the surface next the imaginary middle plane above-mentioned. These arbitrary terms, though applicable only to one determined position of the body, are yet necessary to give tolerable precision to anatomical description: when by their assistance we have made ourselves familiar with the objects they are designed to illustrate, they may be dismissed as easily as they have been adopted; our ideas of the relative situation of parts will be distinct, and may be applied readily to every possible variety of posture. In order to obviate all ambiguity, we shall introduce also the nomenclature of Chaussier, as conveying exact and precise notions of the relations of opposite bones to each other. The terms are generally simple, and always perspicuous as applied to the present subject.

*The upper extremity*—is divided into four parts; the shoulder, the arm, the fore-arm, and the hand, each of which will be separately considered.

The shoulder is the division of the upper extremity attached immediately to the superior and lateral parts of the trunk; it is formed by two bones, one broad, placed vertically behind, called the *scapula*, or shoulder blade, the other long, situated horizontally before, called the *claviclé*, or collar bone. The disposition of these bones gives the broad form and character to the upper part of the chest, which is in itself very considerably contracted at this part, its apparent breadth and magnitude being derived from the lateral apposition of the shoulders. Generally, also, there is a proportion between these and the dimensions of the chest: they are large, and strongly developed, when the latter is well formed; contracted and narrow when it is small or badly shaped. The height of the shoulder depends on the situation of the scapula; it is lower proportionably in the female, and in males of a feeble body, than in individuals of the opposite character. In the latter case, though the bones form the outline, it is the brawny muscles which fill it up, constituting, by their well-defined and massy forms, the distinguishing character of the sex in man, and other animals.

The *scapula*, shoulder blade, or omo-plâte, is a bone of an irregularly triangular figure, seated on the upper and back part of the trunk. It is connected by muscles to the head, the vertebrae, and the ribs, by articulation to the claviclé and humerus. The scapula has such a latitude of motion as to make it difficult to assign precisely its situation on the trunk. But when the arm is at rest, it covers the space between the first and eighth ribs, with its base or posterior margin at a small distance from the vertebral column, to which it approaches nearer above than it does below. At this line the scapula lies pretty close on the ribs; forwards, we find it receding considerably from the opposite surface of the trunk, in which situation it is constantly preserved by its connection with the claviclé.

For convenience of description, we divide the scapula into two surfaces, the dorsal or exterior, and the costal or interior; into three margins or colts, the superior, the posterior, or base, and the inferior, or external costa. The rounded points at which these edges meet are usually called angles, and are named, from their several situations, the superior, the inferior, and the anterior angles of the scapula.

The dorsal surface, the dorsum, or back of the scapula, is divided into two very unequal portions by a strong and solid process of bone projecting from it transversely, called the spine of the scapula. It commences at the posterior margin, about one-fourth part of the whole length below the superior angle, increases gradually in depth as it ad-

## EXTREMITIES.

vances obliquely forward towards the anterior angle, beyond which it projects in the form of a broad, flat process, called the acromion. The spine is connected with the whole breadth of the dorsum, with the exception of that portion of it called the neck; its anterior edge is smooth, rounded, and concave, and is gradually lost in the under surface of the arch of the acromion. The posterior, or projecting ridge of the spine, is broad and flattened, varying however in breadth in different parts. At its commencement is a smooth, triangular space, over which passes a part of the tendon of the trapezius. Further on it is rough, the upper margin of the crista giving attachment to this muscle, the lower to the posterior half of the deltoid. The acromion is flattened in a direction contrary to that of the spine of which it is a continuation, is of considerable breadth, rough and somewhat convex above, concave and smooth below. On the internal edge, which is continuous with the superior crista of the spine, is a smooth oval surface for articulation with the clavicle. The external edge is rough and irregular, giving attachment to the middle part of the deltoid. The summit of the acromion is rounded, and marked by the attachment of a ligament which connects it with the coracoid process. Towards the anterior part of the basis of the spine, near the neck, we observe holes for the admission of the nutrient vessels. The upper surface of the spine is hollow, forming a portion of the supra-spinal fossa, the name given to that portion of the dorsum situated above the spine, and which gives lodgment to the supra-spinatus muscle. The lower surface is also concave, though irregularly so, and contributes to the formation of the infra-spinal fossa, the part of the dorsum lying below the spine, which is occupied by the infra-spinatus muscle; the latter portion scarcely deserves the name of fossa, being convex in its centre. Towards the inferior part of the dorsal surface is a ridge running in the direction of the inferior costa, for nearly its whole length; it gives attachment to an aponeurosis, which separates the infra-spinatus from the teres major, and teres minor. Towards the inferior angle this ridge is met at a very acute angle by another, originating in the inferior costa. The latter forms the line of division between the two last mentioned muscles, the upper and smaller part giving attachment to the teres minor, the lower and broader to the teres major.

The under or costal surface of the scapula is concave, marked by several converging ridges running from the base towards the anterior angle. They give attachment to the aponeurotic divisions of the sub-scapularis, its fleshy bundles lying in the intervening shallow depressions. Towards the superior and inferior angles we mark some projecting points, which give attachment to the serratus major anticus, as also more or less evidently a rising line between, designed for the same purpose.

The superior margin, or costa of the scapula, is the shortest of the three borders. It is thin towards the superior angle, becomes broader as we trace it forwards to its termination in a strong curved process, called, from its similarity to a crow's beak, the coracoid process. At the root of this process we observe a deep notch, crossed by a ligament, so as to form a circular hole; in many instances the circle is completed by bone. It gives passage to the supra-scapular nerve, and usually to a branch of the supra-scapular artery and veins. Just behind this notch the omohyoideus muscle has its origin. The coracoid process is rather flattened, convex and rough above, where it gives attachment to ligaments connecting it with the under surface of the clavicle, concave and smooth below. Its internal edge gives attachment to the pectoralis minor, its exter-

nal to a strong ligament, crossing from it to the acromion, its summit to the united heads of the biceps, and the coraco-brachialis.

The base of the scapula is the longest of the three margins, offering a waving line with an obtuse projection in it, opposite the commencement of the spine; to this, and to the margin below it, the rhomboidei are attached. From its junction with the superior costa results the superior angle, to which the levator scapulae is partly attached.

The inferior costa is much broader than the other, dividing at its anterior part into two projecting lines, with a hollow between them. Towards the inferior angle, where it joins the base, the edge is thinner, and convex, giving attachment to the teres major, and occasionally to some fibres of the latissimus dorsi. The outer of the prominent lines gives origin above to the long head of the triceps; below to the teres minor. The inner line, and intervening hollow, is occupied by the sub-scapularis. The inferior costa terminates above, at the anterior angle, towards the coracoid process, in an ovate, slightly hollowed surface, called the glenoid cavity. This surface is at right angles with the plane of the bone, its long diameter perpendicular, and its broader part below. It is covered by cartilage, the edges raised a little by a fibrous ring, which adds somewhat to its depth. At the upper end of the brim is attached the long head of the biceps. The glenoid cavity is articulated with the head of the humerus; it stands off a little from the body of the bone, supported by a short process, more contracted than the brim of the cavity, called the neck of the scapula. This narrowing is more particularly observable on the back, under the spine.

The scapula is, in its structure, compact; thin and diaphanous every where but at its edges and processes, where the bone is thick and cellular. Its ossification commences at an early period in the foetus, and advances considerably before birth. At the latter period, however, the acromion, the coracoid process, and the base, still exist in the state of cartilaginous epiphyses.

The clavicle, or collar bone, is placed nearly transversely at the superior and anterior part of the chest, between it and the top of the shoulder. In figure it somewhat resembles the italic *f*; the two thirds next the sternum being of an irregularly cylindrical, or nearly prismatic form, and gently convex anteriorly; the third next the scapula flattened horizontally, broad, and with a more considerable convexity directed backwards. It is more slender, and less curved in the female than in the male.

The extremities of the bone are distinguished from their situation by the names of the external or pectoral, and the scapular, or humeral ends of the clavicle. The first of these is triangular, presents an irregular articular surface of considerable extent for connection with the sternum; its plane is nearly at right angles to the body of the bone. The scapular extremity presents also a flat, articular surface, oblong horizontally, accommodated to the opposite one in the acromion. The upper surface is rounded towards the sternum, where the sterno-cleidomastoideus is attached, smooth in its middle portion, flat and broader next the scapula. The under side, to which these characters are equally applicable, is marked near the sternal end, by a roughened surface, for the attachment of a ligament connecting the clavicle to the first rib. Towards the middle is a considerable longitudinal hollow for the lodgment of the sub-clavius muscle. Near the scapular end the face of the bone is unequal, with a rough eminence in it for the insertion of ligaments which bind it to the coracoid process of the scapula. Towards the sternum the anterior edge is broad,

and

## EXTREMITIES.

and bends gently forwards, for about one-half of its length, where it gives origin to a portion of the pectoralis major; it then becomes thinner, slopes backwards, and terminates by suddenly turning forwards again towards its junction with the acromion. It gives attachment to the anterior half of the deltoid. The curvatures of the posterior edge are the inverse of the preceding. The bone is rounded, smooth and concave for the two-thirds next the sternum; unequal and convex towards the scapula, where the trapezius is attached.

The clavicle is in structure like the other long-bones; the medullary cavity is very confined. At the time of birth its form is already strongly marked, and its ossification nearly complete.

*The articulations of the shoulder.*—The scapula is connected with the trunk by a great number of muscles, which partly support it, and allow of all those varied motions of which it is capable. It is closely bound also to the clavicle, which latter bone is immediately articulated with the sternum. We have here only to examine the two last connections, beginning with that between the clavicle and sternum, as forming the union between the shoulder and the trunk.

The sternal end of the clavicle is covered by a cartilaginous crust of considerable thickness, presenting an irregular convex surface. At the upper part of the sternum is an articular cavity, slightly hollowed, of less extent than the opposite articular surface of the clavicle, so that the latter rises considerably above it; a circumstance particularly striking in lean persons.

The ligaments which connect these surfaces are four, an anterior and a posterior, an inter-clavicular, and a costo-clavicular ligament. To complete the joint, we find also an inter-articular cartilage, dividing it into two separate cavities, and a distinct capsular membrane lining each of these.

The anterior ligament covers the front of the joint, lying between the skin and the sterno-mastoideus without, and the capsules immediately within. It is composed of fibres, which descend obliquely from the upper and anterior edge of the clavicle, diverging as they proceed to be fixed into the upper edge of the articular cavity in the sternum. These ligamentous fibres leave several intervals between them, which are occupied by cellular tissue and vessels.

The posterior ligament is smaller and not so strong as the anterior. It separates the sterno-hyoideus and sterno-thyroideus from the capsules to which it firmly adheres. It extends from the posterior edge of the clavicle to the opposite part of the sternum. The fibres descend a little in their passage, diverging as they approach the latter bone.

The inter-clavicular ligament is placed between the two clavicles, immediately above the hollow at the upper edge of the sternum, with the integuments only in front, and the sterno-hyoidei and sterno-thyroidei behind. It is attached to the upper edge of the sternal extremity of each clavicle, the fibres crossing in a flattened form from one to the other, and longer above than below; they are often separated by intervals filled up with cellular tissue.

The costo-clavicular, or rhomboid ligament, passes obliquely upward from the cartilage of the first rib to the internal edge of the under surface of the clavicle, close to its sternal end. It is flat and short, the fibres becoming longer as they recede from the sternum. In front of it lies the subclavian muscle, and immediately behind it the subclavian vein. It has no immediate connection with the articulation, but serves to strengthen it and regulate its motions.

Between the clavicle and sternum we find an intermediate round, flattened piece of fibro-cartilage, its surfaces accom-

modated to the ends of these two bones. Its circumference lying immediately under the ligaments of the joint, is united to the surface of the anterior and posterior. It is united also above and below, by means of a strong and thick fibrous substance, to the circumference of the articular surface of both the clavicle and sternum. The fibro-cartilage is thicker above, and much thinner next the cartilage of the rib. The fibres which compose it are less apparent in its middle than nearer its edges. From its close connection with the surrounding parts, it cannot be moved in any of the actions of this joint.

The capsular membranes adhere to the ligaments which surround the articulation, between the fibres of which they are often apparent. They both adhere also to the fibro-cartilage, one of them lining the cavity between it and the sternum, the other the corresponding cavity between it and the end of the clavicle. The membrane is every where delicate, its inner surface moistened by synovia, which is secreted but in a very small quantity.

From the disposition of the ligaments belonging to this articulation, there remain but few intervals not covered and supported by them; so that it nearly approaches in structure those joints which we find surrounded by a fibrous capsule, as in the cases of the shoulder and the hip, which it somewhat resembles, also in the extent of its motions.

*Articulation of the clavicle with the scapula.*—At the scapular extremity of the clavicle we find a small oval facet, covered by cartilage, corresponding to a similar one in the internal edge of the acromion. We often meet also with a delicate inter-articular cartilage, its superficies sometimes equalling the articular surfaces of the bones, at others less; it is thickest above, and adheres by its circumference to the ligaments. To secure this joint, we find ligaments above and below it; and the clavicle is further bound to the coracoid process of the scapula by strong ligaments, without being any where in contact with it.

The upper ligament forms a broad and flat band, which covers the whole length of the articulation, crossing from the upper edge of one articular surface to the other, the fibres being longer as they are seated more superficially. It lies immediately under the tendinous aponeuroses of the trapezius and deltoid, which form a strong, distinct layer of fibres, not easily separable from the ligament.

Underneath the joint lies another ligament, the fibres following the direction of the preceding, which it approaches in front, being separated behind by an interval filled with cellular tissue. Above, it is in contact with the capsular membrane; below, with the supra-spinatus. The synovial membrane is found lining the articular surfaces, reflected from one to the other, and containing but little synovia. It is sometimes double, where the inter-articular cartilage is perfect.

The ligaments which further connect the clavicle with the scapula are attached to the coracoid process, from which they pursue different directions to be inserted into the clavicle. The most delicate of these has been called the ligamentum bicornis. It arises from the inner edge of the coracoid process, near its point, and, as it advances upwards and inwards, splits into two layers, which envelope the subclavian muscle. The upper band is attached to the clavicle, near the end of the rhomboid ligament; the under layer passes to the rib immediately below it. It is not strong enough to add much to the security of the connection between the bones. The other ligamentous bands, placed between the coracoid process and the clavicle, have been divided by many authors into two distinct ligaments: one, the posterior bundle, has been called, from its figure, conoides; the other,

## EXTREMITIES.

for a similar reason, *trapezoides*. Though scarcely distinct in their origin, they differ so much in figure, and in the direction of their fibres, that we shall consider them as separate ligaments. The posterior ligamentum scapulæ commune conoides is attached below, by the summit of the cone, to the root of the coracoid process; above, to the rough tubercle situated on the under side of the humeral end of the clavicle. It is composed of short thick fibres, radiating as they ascend, parallel to, and continuous with those of the anterior ligament, as they approach nearer the acromion. Below, its fibres are often united with those forming the ligament crossing the notch of the scapula. The anterior ligament, ligamentum commune trapezoides, crosses obliquely from the coracoid process to the clavicle, as a broad flattened band, exceeding the preceding in length. It is fixed below to the posterior part of the upper surface of the coracoid process, above, to an oblique line proceeding from the tubercle towards the end of the clavicle. The anterior fibres are longer than the posterior; the latter, at the union with the fibres of the posterior ligament, form an angle pointing towards the acromion, and leaving in front an angular cavity which is filled by fat. These ligaments are covered by the subclavius in front, by the trapezius behind, leaving an interval of an inch or more towards the scapulo-clavicular articulation.

The scapula has two other ligaments proper to itself, which we shall describe here, although they have no immediate relation with the articulation of the clavicle and scapula. One closes the notch in the last-named bone, the other is extended between the coracoid process and the scapula. The first, consisting of a flat, compact band of silvery shining fibres, crosses from the posterior angle of the notch to the base of the coracoid process, converting it into an hole, through which the supra scapular nerve, and frequently also the supra scapular vessels pass.

The ligament placed between the coracoid process and the acromion is of a triangular form, of considerable surface, thin, and flattened. Its base is attached along the external edge of the coracoid process, from which it proceeds in two distinct bands, separated by cellular tissue, and converging, as they approach the acromion, into one common sheet. The posterior fibres pass obliquely outwards, the anterior are directly transverse; the interval between them is crossed by some scattered slips of ligament. Its upper surface is covered by the deltoid and clavicle, its lower side is in contact with the supra-spinatus. Its anterior edge is not defined, but continuous with a thick and dense layer of cellular membrane, lying between the deltoid and the tendons of the infra and supra-spinatus. This ligament completes the arch formed by the coracoid process and acromion over the shoulder-joint.

*The mechanism and motions of the shoulder.*—The scapula, by its muscular connection with the trunk, is capable of powerful and varied motion; the clavicle, on the contrary, can only follow the impulse communicated by the scapula, whose motions it regulates and limits under certain circumstances. The scapula forms the essential part of the shoulder, the clavicle can be considered only as accessory in man, and some animals who use their anterior extremities for other purposes besides progression. The scapula may in some measure be considered as defending that part of the thorax over which it moves; but its more evident use is to serve as the base of all the motions of the arm, which at the same time it increases most extensively. In this respect it differs from the hip, which is in itself motionless, although affording a point from which the thigh directs all its movements. We shall recur to this difference hereafter: in this place it will be sufficient to notice, that notwithstanding the appa-

rent want of firmness in the shoulder, it is enabled, by means of its numerous and powerful muscles, to offer a solid resistance to the impulse communicated from the arm in any of the violent actions of the upper extremity. The scapula plainly accompanies the motions of the arm, forwards and backwards, but in the simple elevation outwards, and in depression of that bone, its movement is scarcely observable. In the former cases it rotates on an imaginary axis, perpendicular to its plane, placed somewhat about the middle of the bone.

In the instance where the arm passes forward from the state of adduction, the superior angle of the scapula is lowered a little, and approaches the vertebral column, whilst the inferior recedes from it, and is at the same time somewhat elevated. Where the arm is carried backwards the converse of this occurs. In these rolling motions the clavicle is concerned but little if at all; the scapula turning on it at the joint which unites them, the articular surfaces gliding on each other, and the ligaments above and below becoming alternately stretched or relaxed, as the motions are successively continued. They, however, are not capable of resisting alone any violent effort tending to displace the bones in this rotatory motion; it is the strong ligaments crossing from the coracoid process to the tubercle of the clavicle which, by their alternate tension, secure their relations under these circumstances. This articulation is further defended from injury by the mobility of both bones, which would recede before any violent shock.

The clavicle acts as a prop, preventing the shoulder and arm from falling forwards and approaching the breast, either by their weight or by the action of the muscles which move them. It is partly preserved in its situation by muscles which are fixed to it above. Its existence is necessary for many of the motions of the upper extremity, particularly those in which it is carried forward; it favours also the circumduction of the arm, by keeping it at a distance from the trunk, and allows the whole limb to describe arcs of a sphere, the centre of which is found at its sternal end. We find consequently that animals without clavicles enjoy these motions but imperfectly, in many instances in no degree. Their abolition in the case of fractured clavicle is another proof of the utility of the latter in directing the actions of the shoulder.

The combined motions of the scapula and clavicle are those of depression, elevation, those in which the shoulder is carried forward, or backward, and the combination of these or circumduction.

When we raise the shoulder, the scapula passes during its elevation a little obliquely forward. The inferior angle advances, whilst the upper edge or costa recedes from the trunk. The scapular end of the clavicle is necessarily also raised, so as to increase the space between it and the first rib, and to diminish somewhat the angle it forms with the acromion, its sternal end pressing more and more on the articular cavity in the sternum; the rhomboid ligament is stretched, limiting the elevation, and the inter-clavicular ligament relaxed.

In depressing the shoulder the exact inverse of these effects is produced, and requires not therefore a minute detail. We shall observe only that the lower surface of the clavicle may be brought so near to the first rib, as to compress the intervening vessels very considerably, and produce a painful swelling of the arm. The depression is much limited by this contiguity of the rib, which lies pretty close to the clavicle in the most common and easy position of the shoulder.

When the scapula advances forwards its anterior angle recedes from the trunk, being kept off by the clavicle, the base at the same time approaching nearer the breast. The clavicle becomes more distant from the first rib in the horizontal:

## EXTREMITIES.

horizontal direction, the inter-clavicular, and the posterior ligaments are rendered tense, the sternal end pressing inwards and backwards. In this situation luxations have occurred, but the accident is rare, as the shoulder is seldom exposed to any violence under these circumstances, that by its direction would probably effect it.

In carrying the shoulder backward, the anterior angle of the scapula is brought nearer to the chest, and the base approaches the spine. As the scapula has a considerable extent of motion in this direction, and is accompanied by the scapular end of the clavicle, it will readily be conceived, that if the movement is sudden and violent, the sternal end will distend its anterior ligament, may rupture it and become luxated forwards on the sternum. In fact this is the most common mode of displacement.

The shoulder may be moved in any of the intermediate directions to those we have described; and in all we are to consider it as a lever composed of two parts, one horizontal, the other vertical, the sternal end of the clavicle being the resting point, or the centre of the movements of the lever. The continued succession of all these motions produces the circumduction of the shoulder, a motion in which the clavicle describes a cone, the summit of which will be at its sternal, and the base traced by its scapular extremity. We are not to confound this motion of the shoulder with that of rotation, described above.

The direction of the shoulder is subject to variations from the slightest motion; in general it is so inclined that the glenoid cavity points outwards, proving most evidently, if any argument were wanting, that the upper extremities are not designed to support the body in the attitude of a quadruped. In fact, in that position, the head of the arm bone would press, not against the glenoid cavity, but on the capsular ligament which surrounds it, and which is utterly incapable of long resisting the effort.

*The Arm.*—The humerus, the only bone in the arm, the largest and strongest of those of the upper extremity, is placed between the shoulder and the fore-arm. It is nearly straight, bending gently forwards below, “*tanquam ad meliorem amplexum*,” says Albinus. Of an irregular prismatic form, somewhat rounded at its upper and middle portions, flattened and gradually widening below, so as to be broadest at its lower end where it supports the fore-arm. It has the appearance of having been twisted in the middle, as if at an early period the upper end had been carried round forcibly outwards, and the lower end in the opposite direction. We divide it into two extremities, a superior or scapular, and an inferior, or cubital; and into a middle portion or body.

At the upper end, the most bulky part of the bone, are three eminences; the head, and the great and small tubercle of the humerus. The head of the humerus is rounded, forming nearly the half of a sphere, smooth, covered by cartilage, articulated with the glenoid cavity of the scapula. It stands on a very short process, somewhat more contracted than the articular circumference, called improperly, perhaps, the neck of the humerus. The head and neck are directed obliquely upwards, so that a line drawn in their axes would form an obtuse angle with the body of the bone; they are also inclined backwards with respect to the plane of the condyles at the lower extremity. From this oblique position of the head with regard to the body of the humerus, the neck is longer, and the contraction more strongly marked below than it is above, where we remark only a shallow groove dividing the head from the tubercles.

The great tubercle is placed externally, opposite to the head. It is rough, broad, and flattened; marked by three

distinct surfaces for the attachment of tendons. One, anterior, for the tendon of the supra-spinatus muscle; a middle spot, for that of the infra-spinatus, and one below for the teres minor. The lesser tubercle, placed in front of the bone, is rough, much smaller but more elevated than the last. It gives attachment to the sub-scapularis. Dividing the tubercles is a deep longitudinal groove, of which we shall speak below.

The body of the humerus, though of a very irregular form, is sufficiently marked for us to divide it into three differently inclined surfaces, and as many projecting lines between them. Owing to the twisted figure of the bone these angular lines pursue rather a spiral than a straight course.

The anterior ridge or spine commences at the inner edge of the great tubercle, and is continued through the middle of the bone to the lower end. It is rough in its upper half, giving attachment above to the pectoralis major, and lower down to a portion of the deltoid: below it is rounded and smooth, giving attachment to and covered by the brachialis internus. The internal line descending from the small tubercle, gives attachment above to the latissimus dorsi, and lower down to the coraco-brachialis and triceps. Towards the anti-brachial extremity it becomes much more prominent, affording attachment to a strong inter-muscular aponeurosis. The external edge begins at the under side of the neck, running obliquely forwards as it descends. It is but faintly marked above where it gives attachment to a portion of the triceps; is interrupted towards the middle, leaving a smooth flat surface, over which the radial nerve and accompanying vessels turn; below it rises again into a more acute, and elevated ridge, which gives attachment to an inter-muscular ligament, and some muscles belonging to the fore-arm. In the internal surface, bounded by the anterior and inner lines, we observe above the bicipital groove, continued between the tubercles and the spines, proceeding from them for some way down the bone, increasing in breadth, and gradually becoming obliterated. It is lined by cartilage, and provided with a synovial membrane, where it lodges the tendon of the long head of the biceps. Towards the lower end of the groove, at its outer side, is a rough line for the insertion of the tendon of the teres major. About the middle of the internal surface the coraco-brachialis has an attachment, and below this the brachialis internus. The external face is larger than the preceding: covered above by the deltoid, strongly marked by a rough prominence intersecting it obliquely for the insertion of this muscle. Immediately below this ridge is a broad shallow oblique depression, along which the radial nerve and some vessels pass. Towards the lower extremity the bone is slightly concave, and gives attachment to the brachialis internus. The posterior surface is smooth and rounded, altering its direction in a considerable degree as we trace it downwards: it gives origin to and is covered by the triceps.

The lower, or anti-brachial extremity of the humerus, is broad and flattened transversely, and advances a little forwards from the axis of the body of bone. In the middle is an articular surface for connection with the fore-arm, and on either side a projecting point, called tuberosity, or condyle. Of these the internal (posterior of Albinus) is the most projecting. It is somewhat flattened, continuous above with the internal spine, marked irregularly below by the attachments of muscles, and the internal lateral ligament of the elbow joint. The external condyle (prior Albinus) is much less prominent, and gives attachment to the external lateral ligament, as well as to several muscles which lie on the radial and dorsal sides of the fore-arm.

## EXTREMITIES.

The articular surface, placed between these two points, descends a little way beyond them. It is marked by several eminences and hollows. Next to the external condyle is a rounded eminence (capitulum of Albinus) adapted to the hollow in the head of the radius, and at its inner side is a groove for the internal projecting edge of that hollow. The remaining division forms the pulley or trochlea (rotula of Albinus) for articulation with the ulna. We observe two prominent edges and a depression between them. The edge next the radius is not so prominent in front as behind, neither does it rise so high as the edge next the internal condyle, which descends a considerable way below the rest of the articular surface, sloping gradually into the hollow of the pulley on one side, and terminating abruptly by an acute margin on the other. The hollowed part, forming nearly three-fourths of a circle in extent from before backwards, is much broader behind, directed from thence obliquely inwards as we follow it to the front of the bone. Above the middle of the pulley, at its back part, is a deep cavity, oblong transversely, which receives the olecranon, or extremity of the ulna, during the extension of the fore-arm. Opposite to this, at the termination of the pulley in front, is a smaller hollow for the reception of the coronoid process of the ulna, when the fore-arm is bent. Between these corresponding hollows there remains but a thin plate of bone, in many instances diaphanous.

The humerus resembles in structure the other long bones. Its ossification commences at three points; at the middle and at each end. At the time of birth the scapular extremity of the humerus is entirely cartilaginous, and of greater proportionate bulk. At the lower extremity the capitulum is much larger in comparison with the trochlea than in the adult bone.

*The articulation of the humerus with the scapula, forming the shoulder joint.*—The head of the humerus is covered by a layer of cartilage, much thicker in the middle than at the circumference. The glenoid cavity of the scapula is lined by cartilage, thinner in the middle than round its edges. The margin of the cavity is further provided with a fibrous elevated border, proceeding above from the tendon of biceps which gives off a bundle on either side; below, from the circumference of the articular cavity. Over the joint is the bridge formed by the acromion, the coracoid process, and the ligament stretched across between them. The head of the humerus moves on the glenoid cavity; but from the small relative size of the latter, the surface of the head of the humerus in contact with it forms but a small part of its articular superficies, the remainder of which is thus out of the cavity, and corresponds to the capsular ligament.

The capsular or orbicular ligament encloses the whole of the joint in the form of an oblong sac, contracting a little at each extremity. The upper edge is fixed round the glenoid cavity of the scapula, beyond the fibrous ring we have just mentioned. In some instances there is an interval left on the inner side, which is then supplied by the tendon of the sub-scapularis. The lower edge is attached round the neck of the humerus; close to the margin of the articular cartilage above, at a greater distance from it below. The attachment is interrupted between the two tubercles, the ligament crossing from one to the other over the bicipital groove. The deficiency occasionally observed on the inner side is supplied as above by the tendon of the sub-scapularis, which may be seen from within the joint covered only by the reflected synovial membrane. The capsular ligament is remarkable for its length, which allows the articular surfaces of the two bones to be separated from each other, by the distance of an inch, on the admission of air into the

cavity. It is covered above by a dense ligamentous band passing from the outer edge of the coracoid process, to the anterior part of the larger tubercle, where it unites with the tendon of the supra-spinatus; and so closely joined by its under surface to the capsular ligament, that, but for its attachment to the coracoid process, it would be difficult to make any distinction between them. It is this accessory band which makes the capsular ligament thicker above than in any other part. The shoulder joint is further strengthened by the tendons of the supra-spinatus, infra-spinatus, teres minor, and sub-scapularis, which surround it, and which are firmly united to different parts of the capsular ligament. The latter is in contact also with the deltoid above, and the origin of the long head of the triceps below. It is formed by fibres running in various directions, and crossing each other, is thinnest where covered by the infra-spinatus, and teres minor, stronger on the inner and under sides; apparently insufficient to secure the firmness of the articulation, if not supported by the muscles proceeding from the scapula. The synovial membrane is spread over its internal surface, and reflected over the articular cartilages. At the edge of the bicipital groove a process goes from it, which descends along the groove, lining it for the space of about an inch. It is then reflected on all sides over the tendon of the long head of the biceps, and continues to give it a covering in its passage through the joint to its attachment above the glenoid cavity. By the reflection of the sheath below, the escape of synovia is prevented, and the tendon may still be said to be exterior to the cavity of the joint.

*The mechanism of the shoulder joint as to mobility and resistance.*—Although motion be the principal office of the upper extremity, there are many accidental circumstances in which firmness of opposition is as necessary as in the lower, and the means nearly as complete.

The motions of the arm are very extensive, generally combined in different degrees with those of the shoulder. Indeed so great is its mobility, that it escapes on that account many injuries it would otherwise be liable to, from the looseness of its articulation with the shoulder. Add to this that the point of support, the glenoid cavity of the scapula, is in itself so moveable, as further to modify and lessen the effects of external impulses. We have before observed that the scapula more particularly accompanies the arm in its motions backwards and forwards, less so in its elevation outward and depression; the clavicle necessarily partakes of the movement, and from this disposition two advantages are derived that the circuit of motion is enlarged, whilst tendency to displacement is diminished by the distribution of the effort over three points instead of one.

The arm, and consequently the whole limb, may be elevated, depressed, carried forward, backward, and in all the intermediate directions; it may be rolled also on its axis in any of these conditions.

When the arm is raised, the head of the humerus glides from above downwards in the glenoid cavity, in some measure abandons it, and rests against the lower side of the capsular ligament, which it distends more or less according as the scapula has accompanied it in its movement. If the arm be elevated outwards or abducted, it cannot be much assisted by the scapula; the great tubercle is buried under the arch formed by the acromion, the coracoid process, and the ligament between them, and in this situation the capsule is particularly stretched, is liable to be torn, and the arm luxated downwards. When the arm is thus raised above the horizontal line, at a distance from the trunk, the weight of the body brought to bear with force on the head of the bone, as in the case of falling, tends to de-

## EXTREMITIES.

press it; and at the same time the actions of the pectoralis major, latissimus dorsi, and teres major, concur in producing the same effect; since they have their fixed points in the trunk, and their moveable point in the humerus. Luxation, under these circumstances, is by no means rare. The action of muscles alone is scarcely adequate to the effect, which is generally the consequence of some violent impulse.

In depression or adduction, the arm returns to its natural position, in which displacement is almost impossible. Where the limb is perpendicular, any external impulse acting on its lower end, would only press the head of the bone firmly against the arch of the acromion. The only mode in which it could be made to pass beyond the arch, would be by carrying the lower end inwards; but this is opposed by the trunk, so that in this position of the arm luxation upwards is effectually prevented.

When the arm is carried forward to a considerable height, it is accompanied in its motion by the rotation of the scapula, and the head of the bone scarcely quits the glenoid cavity. It is on these accounts that when in falling forward the arm is projected considerably beyond the head, luxation is rarely the consequence, though the shock be severe. In the motion backwards the head of the humerus quits in some degree the articular cavity, and bears against the capsular ligament and the tendon of the sub-scapularis. The extent of this motion is also increased by the coincident movement of the scapula, and at the same time the probability of luxation diminished; it is not, however, so free as the motion forwards.

Circumduction, or the succession of these motions, is enjoyed extensively in the joint of the shoulder; the execution of it in the anterior half of the circle is more easy, because more unconfined than in the posterior. And we may observe as a general axiom, applicable to all the motions of the arm, that the movements forwards are far more extensive than those in the contrary directions, whatever be the point from which they commence, in whatever direction the limb may be; examples of these are too familiar for us to particularize them, the cause will be readily understood from our account of the mechanism of this part of the upper extremity.

The rotation of the arm takes place exclusively in the shoulder joint, not accompanied as the others by any corresponding motion of the scapula and clavicle. In this motion the head of the humerus merely glides backwards or forwards in the glenoid cavity, according as it is rolled inwards or outwards; it is not extensive, and cannot give occasion to displacement of the bones. In cases where the functions of the elbow joint have been so far destroyed, as to prevent the rolling of the bones of the fore-arm one over the other, the rotation of the humerus has been observed to be more marked, to compensate the deficiency.

The fore arm, placed between the arm and the hand, is composed of two bones, the ulna and radius.

The ulna, the largest of the two, is on the inner side. Irregular in shape, strong, and larger above, lessening gradually in size to its lower end. We divide it into two extremities, an upper or humeral, a lower or carpal; and into a middle portion or body.

The humeral extremity comprises two strongly marked eminences, the olecranon and coronoid processes, and two lunated cavities, the largest articulated with the pulley in the lower end of the humerus, the lesser with the head of the radius. The olecranon projects beyond the coronoid process in a line with the body of the bone; it is strong, somewhat curved, rough above, where it affords attachment to the triceps; smooth behind, where it lies immediately

under the skin; concave before, where it forms the upper part of the great sigmoid cavity. The coronoid process stands opposite to the olecranon in front of the bone. Its upper surface forms the lower part of the last named cavity, the under is marked by the attachment of the brachialis internus. The edge next the radius is hollowed by the lesser sigmoid cavity, the opposite margin is acute, and gives attachment to the pronator teres, the flexor sublimis, and the internal lateral ligament of the elbow joint. The great sigmoid cavity (sinus lunatus of Albinus) lies between these processes. It is deeply concave longitudinally, adapted to the figure of the trochlea of the humerus; divided transversely in the middle by a contraction of the articular surface, and a faintly marked line between the narrowed points. The upper division made by the olecranon is the largest. The cavity is divided also into two unequal portions, by a convex line traversing its whole length, the internal division is the largest, and most hollowed, for the reception of the inner border of the trochlea. The lesser sigmoid cavity is oval transversely, slightly hollow, continuous above with the larger cavity.

The body of the ulna is of an irregular prismatic form, largest above, curved gently forward, and turning towards the radius below. We distinguish in it three surfaces, and a like number of angular ridges between them. The anterior edge or spine passes from the lesser sigmoid cavity in a curved line to the carpal extremity; it is acute above, and gradually softened below, till it becomes scarcely visible. It gives attachment to the interosseous ligament. The internal edge (posterior, Alb.) is rounded, giving attachment to the flexor profundus above, to the pronator quadratus below. It follows a curved line from the inside of the coronoid process, and is somewhat more prominent below, for the attachment of the latter muscle. The posterior edge (exterior, Alb.) beginning from behind the olecranon, is strongly marked in its upper two thirds, and insensibly lost below. It gives attachment to an aponeurosis. The anterior surface (latus interius, Alb.) is broader above than below, gibbous in the middle, and concave at each end; the hollow part below is occupied by the pronator quadratus, the remainder gives attachment to flexor profundus. Towards the upper end is a small hole directed upwards for the admission of the nutrient vessels. The posterior surface (prius, Alb.) is divided through its whole length by a prominent line; at the upper end of the internal division is a triangular space for the attachment of the anconæus; below it is covered by the extensor carpi ulnaris. The external division, that nearest the radius, gives attachment above to the supinator brevis, below to the extensors of the thumb and fore-finger. The internal surface is broad, and a little concave above, giving attachment to the flexor profundus, convex and much narrower below, lying immediately under the skin.

The carpal extremity is small, marked by two eminences; one placed externally, called the head or capitulum, the other, from its shape, the styloid process. The head presents a rounded articular surface, corresponding below to a triangular inter-articular cartilage placed between it and the carpus; externally to an articular cavity in the inner side of the carpal extremity of the radius. The styloid process projects beyond the head; it is small, of a conical shape, the point giving attachment to the internal lateral ligament of the wrist. Between these processes is a transverse groove, which gives attachment to the fibro-cartilage just mentioned. Behind they are separated by another longitudinal groove, which lodges the tendon of the extensor carpi ulnaris.

The ulna is formed from three points of ossification, as the

## EXTREMITIES.

Other long bones. At the time of birth the form of the olecranon is fully determined, whilst the coronoid process projects but little. The consequence is, that the great sigmoid cavity is less concave in comparison than in the adult, and the lesser sigmoid cavity is proportionably small and shallow.

The radius is situated on the outer side of the fore-arm. It is shorter than the ulna; smaller above than below, and gently curved in the middle. The upper or humeral extremity, called also the head of the radius, presents a circular articular surface; slightly hollowed in the middle, corresponding to the rounded eminence on the cubital end of the humerus. The smooth articular surface is continued a short way down the bone, and is broadest on the inside, where it lies in the lesser sigmoid cavity. This division is supported by a narrower portion of bone, cylindrical, and of an inch in length, called the neck of the radius. Immediately below, on the inner side, is an oval protuberance, smooth on its anterior half, over which the tendon of the biceps passes, separated from it by a bursa mucosa; rough posteriorly where this tendon is inserted.

The body of the radius is of an irregular prismatic form, which makes a natural division of it into three faces, and as many angular lines. The anterior edge is more prominent above than below. The upper part gives attachment to the long flexor of the thumb, to the flexor sublimis, and to the supinator brevis; its lower to the pronator quadratus. The internal edge or spine, acute in the middle, rounded at each end, gives attachment to the interosseous ligament. The posterior, prominent also in the middle, and disappearing insensibly above and below, gives no muscular attachments. The anterior surface is concave above, where it gives origin to the flexor longus pollicis; a little convex below, where the pronator quadratus is fixed. About its middle is the hole for the nutrient vessels of the bone. The posterior surface, like the former, increases gradually in breadth from above downwards, is irregular, gives attachment above to the supinator brevis, and lower down to the extensors of the thumb; its inferior part, covered by the extensor communis, the extensor tertii internodii pollicis, and the indicator. The external surface is convex throughout. Its upper third gives attachment to the supinator brevis; about its middle is a rough eminence, into which the pronator teres is implanted; below it is covered by the radial extensors of the carpus.

The carpal extremity is larger than the superior, irregularly quadrilateral, the longest side anterior. We observe in it an articular cavity, oblique, slightly hollowed, crossed by a rising line from before backwards, adapted to two of the bones of the carpus; the outer division to the os scaphoides, the internal to the semi-lunare. The anterior edge of the cavity is rough for the insertion of ligaments. The posterior offers two grooves; the internal, broad and superficial, gives passage to the extensor communis and indicator, the outer, narrow and deeper, follows an oblique course from within outwards and downwards: through it passes the extensor tertii internodii pollicis. On the inner margin is a lunated articular surface, corresponding to the capitulum of the ulna. The outer side, divided from the posterior by a rising spine, is marked in a similar manner by two hollows. The anterior offers two grooves for the extensores primi and secundi internodii pollicis; the posterior is marked by the tendons of the radial extensors. At the sharp ridge, between this side and the anterior, the supinator longus is implanted. The prominence between the hollows is continued downwards into a blunt process, passing beyond the articular surface, called the styloid process of the radius. It gives

attachment to the external lateral ligament of the wrist. The radius resembles, both in its formation and structure, the other long bones. At the time of birth its extremities are yet cartilaginous; the lower end is soonest completely ossified.

*The elbow joint; the articulation of the ulna and radius with the humerus.*—The lower end of the humerus presents an articular surface composed of alternate eminences and depressions, covered by a continued crust of smooth cartilage. The great sigmoid cavity of the ulna is lined by cartilage, interrupted in the middle by a transverse contraction and groove; continued into the lesser sigmoid cavity. The head of the radius is also covered by cartilage, continued over its circular margin for a short way down its cylinder. The humeral end of the ulna corresponds to the pulley, that of the radius to the capitulum at the lower extremity of the humerus. These surfaces are bound together by ligaments, and covered by a synovial membrane reflected from one to another.

The ligaments which more particularly secure the joint are called lateral, one being placed on its outer, the other on its inner side. The internal lateral ligament is fixed above to the internal condyle of the humerus. It radiates as it descends, dividing into two portions; the anterior is fixed to the inner side of the coronoid process of the ulna, the posterior, the smallest of the two, to the olecranon. The anterior division is covered by the tendon common to the muscles proceeding from the internal condyle, and is partially united to it. Immediately under the ligament is the capsular membrane. The external lateral ligament can with difficulty be distinguished from the common tendon of the muscles attached to the external condyle. It is fixed above to this condyle, below it is united to a large portion of the circle of the annular ligament of the radius. It is not so strong, so large, nor so clearly defined as the internal lateral ligament, its fibres diverge considerably, and are in contact with the synovial membrane. In addition to these ligaments we find scattered bands of fibres traversing in different directions, both before and behind the articulation; their irregularity scarcely admits of description. Between them and the synovial membrane lie some cellular tissue and fat. This synovial membrane is reflected from the humerus close at the margin of the articular cartilage, and is continued under the ligaments to the opposite surfaces of the ulna and radius, lining the sigmoid cavities of the first, and spread over the head of the latter. It is common therefore to the articulations of the fore-arm with the arm, and of the bones of the fore-arm between themselves. This joint is strengthened also in a remarkable degree by the numerous muscles which are attached round it, and which cover it on every side.

*The motions of the fore-arm on the arm*—are confined to flexion and extension, the ulna executing the principal part, the radius necessarily following the same direction. In a state of complete flexion the coronoid process of the ulna and the prominent margin of the head of the radius are found corresponding to the opposite hollows in front of the humerus, the olecranon below the condyles, having moved a considerable distance from the internal one. At this time the lateral ligaments are relaxed; the posterior half of the trochlea of the humerus in contact with the capsular membrane, reflected from it to the olecranon, and protected by the triceps. Under these relations the joint is secure; displacement in any direction would be almost impossible, without some fracture of bone. In the intermediate states between flexion and extension the articulation has not the same appearance of security; but from the great mobility of the lower end of the humerus; from its receding easily

## EXTREMITIES.

before every shock when the fore-arm is in such situation, we seldom meet with a dislocation of the latter under these circumstances. In the extension of the fore-arm on the arm, the radius and ulna glide backwards over the articular surface of the humerus, until stopped by the olecranon becoming locked in the cavity adapted for its reception in the latter bone. At this time the lateral ligaments are tightened as well as the capsule in front of the joint. It is in the state of complete extension that luxations most usually occur, the humerus passing down in front of the bones of the fore-arm. This frequently happens in a violent fall on the hands. The whole weight of the body is carried forwards with considerable impetus on the arms which are stretched out to save the head from coming to the ground. In this case the fore-arm is fixed, and the humerus, following the impulse of the body, ruptures the ligaments, and is thrust forwards, the olecranon opposing itself to all displacement backwards. It would appear also, that a dislocation might occur from lifting a heavy weight with the arm fully extended; but here the effort is voluntary, and the pain felt in the bend of the elbow is a sufficient warning to desist. When the fore-arm is extended it forms an obtuse angle with the arm, and when bent it is not found in the same line with the humerus, but slants a little inwards towards the breast. Both these circumstances depend on the obliquity of the pulley at the lower end of the humerus. This direction of the fore-arm, and consequently of the hand in the state of flexion, is particularly observable in man, and necessarily requires the existence of a clavicle, without which the fore-arm, when bent, would be carried to the opposite shoulder. Thus in the different ranks of animals the existence of a clavicle, and the motion of pronation, are found generally connected with this obliquity in the flexion of the fore-arm. In the state of demi-flexion we may observe a slight lateral motion of the fore-arm on the arm, which cannot take place in the states either of complete flexion, or extension.

*The articulations of the radius with the ulna.*—These bones are in immediate contact at their humeral and carpal extremities; between these points there is a vacancy occupied by a flat interosseous ligament. Above, the head of the radius is received into the lesser sigmoid cavity of the ulna; below, it offers a shallow articular surface, which revolves on the capitulum at the carpal end of that bone. First we shall examine the articulation at the humeral ends. It is lined by the synovial membrane common to it, and to the articulation of the fore-arm with the arm, and secured by a strong flat circular band of fibres, called the annular or orbicular ligament of the radius. This ligament forms three-fourths of a circle, which is completed by the lesser sigmoid cavity, and in which the head of the radius turns. It is about three lines in breadth, fixed before and behind to the ends of the lesser sigmoid cavity, lost insensibly above over the surface of the synovial capsule, to which it is firmly united, terminating by a more defined edge below. It is composed of parallel circular fibres, into which the external lateral ligament is fixed from above, as also some oblique fibres proceeding from the olecranon, the ligamentum adcesorium posticum of Weitbrecht. The annular ligament is of a dense compact texture, frequently cartilaginous in advanced age. It lies immediately over the synovial membrane, but is no where connected in any degree with the radius. It is covered by muscles.

The space between the upper and lower articulations is filled by the intervention of ligamentous fibres, which further secure the relations between the radius and ulna. A portion of these has obtained the name of the oblique ligament, or chorda transversalis; the remainder is included

under the general term of interosseous ligament. The oblique ligament, a small and flat band of fibres, passes obliquely from the inner edge of the coronoid process below the lesser sigmoid cavity to be inserted into the radius at a point which lies just below its tubercle. In this course it accompanies the inner edge of the tendon of the biceps, its direction being opposite to the fibres of the interosseous ligament, and in a plane anterior to them. Between this ligament and the head of the radius there is left a triangular space filled by cellular tissue, in which the tubercle of that bone revolves. The interosseous ligament commences below the tubercle attached to the inner ridge or spine of the radius, from which the fibres pass obliquely downwards and inwards to be attached to the opposite spine of the ulna. It is composed of flat parallel fibres, leaving various intervals for the passage of vessels. It is covered on both its surfaces by the deep seated muscles of the fore-arm, to which it affords attachments. It is more delicate above, insensibly losing its shining appearance, and interrupted by a large vacancy, which gives passage to the posterior interosseous vessels; stronger below, where we find another opening for the passage of the anterior interosseous vessels. On the posterior surface of this ligament, and more especially at the upper end, we often find flat bands of fibres decussating it: they have been described under the name of the posterior transversal chord.

The inferior articulation between the radius and ulna, or that at the carpal ends of these bones, is provided with a synovial capsule, and a triangular fibro-cartilage interposed between the ulna and the bones of the carpus, and filling the vacancy observed between them in the skeleton.

This triangular cartilage is fixed by its base to the prominent edge which divides the articular cavity at the bottom of the radius, from that which receives the capitulum of the ulna. It is attached by its summit to the groove between the capitulum and the styloid process. Its edges are united to the synovial membranes of both articulations, the radio-carpal and the radio-cubital. Its upper and lower surfaces are concave and smooth, the superior corresponding to the lower surface of the ulna. It is occasionally incomplete at the base, allowing of the contact of the two capsular membranes just mentioned.

The capsular membrane is loose, so as not to impede the extended rotation of the radius. It is continued from the upper surface of the inter-articular cartilage over the articular surfaces of the radius and ulna. It is sometimes covered here and there by a few scattered ligamentous fibres, which are in many instances scarcely observable.

*The motions of the bones of the fore-arm, between themselves and their powers of resistance.*—We have hitherto considered the fore-arm only in its relation to the arm, in which the ulna was more essentially concerned; the movements in the present case depend chiefly, and almost exclusively, on the radius, and are necessarily communicated to the hand with which it is articulated below, the ulna concurring but little in the construction of the joint of the wrist. These bones are thus disposed inversely as to importance in the joints of the elbow and wrist: above, the ulna plays the principal part, the radius being accessory only; whereas below, the ulna is of comparatively little importance, the radius of the greatest. Their form is accommodated to the different use of each: the ulna large above and small below; the radius of little volume at its upper extremity, broad and solid at its lower, where it supports the hand. This double opposition in the form of the bones is not only accommodated to their functions, but renders the solidity of the fore-arm nearly equal throughout.

## EXTREMITIES.

out: The radius, however; from its more direct connection with the hand, more immediately sustains any effort impressed on the latter, as in pushing violently; or falling, and is often fractured under such circumstances. Still the result of the general mechanism will be, that the same bone, not having to support the motions of the two joints, the elbow and wrist, motions which are often simultaneous, fractures and dislocations are the less likely to occur.

The radius may be rolled on the ulna inwards and outwards. In the former case, supposing the radius to be horizontal, the palm of the hand is turned downwards, and the motion called on that account pronation; in the latter it is turned upwards, and the motion called supination. In pronation, which is the most common position, the humeral end of the radius turns on its axis in the hoop formed for it by the lesser sigmoid cavity and the annular ligament, while the carpal extremity rolls over the lower end of the ulna, tracing an arc of a circle. In this state the relative situations of the bones are changed, the radius crossing the ulna, and diminishing the space between them. If pronation be carried forcibly too far, a dislocation may take place in either articulation; more readily in the lower, on account of the greater extent of motion, and less strength of restraining ligaments; in the upper, the radius does not quit its situation, and is secured by a very strong ligament, besides the powerful support of the muscles attached round it. In supination the radius moves in the contrary direction, until it becomes parallel to the ulna, beyond which it cannot go. If it is forced beyond these limits a dislocation of one of the articulations must ensue, most probably of the lower. A great obstacle to luxations of this joint, either in pronation or supination, is found in the triangular fibro-cartilage at the lower end of the bones, which is very strong, and which must necessarily be torn.

Although at first sight one might be disposed to imagine the ulna an immoveable fulcrum, round which the radius rolls, it is certain that in pronation the carpal end of the ulna passes outwards, in supination in the contrary direction, so that it traces arcs of a circle in a contrary way to the carpal end of the radius. Of this any one will be effectually convinced by observation or experiment. But as the ulna cannot roll on the lower end of the humerus, it necessarily involves the latter bone in the execution of these motions, which it thus assists by its powers of rotation. Pronation and supination then depend not only on the rotation of the radius, but on the opposite motion of the ulna, and the rotation of the arm. The latter of these is very much more sensible if the motions take place when the fore-arm is extended on the arm, than when it is bent: in the former case, from the disposition of the bones and ligaments, any rotatory motion of the ulna is impossible, in the latter it may exist in a slight degree.

We have observed that the disposition of the bones of the fore-arm is such as to offer the best possible resistance to external efforts: nor is their position as to these motions less favourable, the head of the radius lying a little before the ulna, and the breadth of its carpal extremity removing its axis from the lower end of the ulna, so as to increase and facilitate the pronation and supination of the hand, offering at the same time a broad basis for its support.

*The hand*—forms the fourth and last division of the superior extremity; it is articulated with the lower end of the fore-arm. It varies considerably in size and form in different individuals: most commonly is comparatively smaller in females. We distinguish in it two surfaces, a dorsal and a palmar; two edges, a radial and ulnar; and also an upper or anti-brachial, and a lower or digital

end. It is composed of twenty-seven bones, which have been arranged under the different titles of carpus, metacarpus, and fingers.

*The Carpus*.—The carpus, or wrist, is oval transversely, convex on its dorsal, hollowed on its palmar surface, where it gives passage to the flexor tendons. This hollow is bounded laterally by four eminences resulting from different bones of the carpus, which give attachment to a strong ligament confining the tendons in their situation. It is convex at the edge next the fore-arm, offering a number of irregular articular surfaces at the border next the metacarpus. It is formed by two rows of small irregularly shaped bones, the upper range called anti-brachial, the lower metacarpal. Each of these ranges is composed of four bones; those in the anti-brachial row, commencing from the radial edge, are the scaphoides, lunare, cuneiforme and pisiforme; in the metacarpal row the trapezium, trapezoides, magnum and unciforme. Although varying much in figure, they have some characters in common, which allow of our describing them with tolerable precision, without rendering confused or obscure our ideas of their mutual relations. We distinguish in each bone six surfaces, or sides; an upper or anti-brachial, a lower or metacarpal, an anterior or palmar, a posterior or dorsal, an outer or radial; and an inner or ulnar.

The scaphoides, so called from a supposed resemblance to a boat, is the largest bone of the first row. It is somewhat oval in figure, the long axis being directed obliquely from above outwards and downwards. The upper surface is convex, triangular, articulated with the radius; the lower is also convex, corresponding to the opposite surfaces of the trapezium and trapezoides. The posterior narrow, and grooved by the insertion of ligaments; the anterior long and contracted, concave towards the fore-arm; convex and projecting below, forming one of the eminences before mentioned. The outer, or radial side, is rough for the attachment of the external lateral ligament of the wrist; the internal presenting a double articular surface, the upper narrow and convex, connected with the os lunare; the lower broad and concave, forming part of the articular cavity for the reception of the os magnum of the second row.

The lunare, or semi-lunare, has obtained its name from the figure of one of its articular surfaces, which resembles a crescent. It is not so elongated in form as the last bone; convex and triangular above when articulated with the radius; concave below, narrowest in its transverse diameter, articulated with the os magnum, and in a small degree with the unciforme; rough and unequal on the anterior and posterior surfaces for the attachment of ligaments, the anterior side the smallest; the outer face narrow, smooth, in the form of a crescent, with the convexity upwards in contact with the scaphoides; the inner also smooth, plane, articulated with the cuneiforme.

The os cuneiforme (triquetrum of Albinus) less in volume than the preceding, oblong and somewhat pyramidal in shape, its base next the os lunare, its apex directed obliquely inwards and downwards. The upper surface is convex, articulated with the bottom of the ulna by the intervention of the triangular fibro-cartilage before mentioned; the lower oblique, concave, articulated with the unciforme; the anterior presents on its inner side a flat circular articular facet articulated with the pisiforme, on its outer it is rough for the attachment of ligaments; the posterior and internal are also unequal and rough for similar purposes; the external or radial surface is plane and smooth, articulated with the lunare.

The os pisiforme (subrotundum of Albinus) has obtained its

## EXTREMITIES.

its name from its rounded figure. It is the smallest of the bones of the carpus. On its posterior surface we observe a slightly hollowed articular surface, where it rests on the last described bone, "*affidens patellæ in modum, aut sesamoidei*," (Alb.) With this exception the bone is convex on all sides, projecting beyond the plane of the other carpal bones, rough, and unequal, giving attachment above to the flexor carpi ulnaris, below to the abductor of the little finger, and before to the annular ligament of the wrist. It constitutes one of the four prominent points of the palmar side of the carpus.

The trapezium (*multangulum majus*, Alb.) is the first bone on the radial side of the second range of carpal bones, and lies somewhat anterior to them. Above it offers a concave articular surface, semi-circular, opposed to the scaphoides; below another, convex antero-posteriorly, concave transversely, articulated with the metacarpal bone of the thumb; on the front rough, with a deep groove at the upper end for the passage of the flexor carpi radialis; the outer edge of the groove giving attachment to the annular or transverse ligament, and forming one of the eminences already mentioned; on the back and outer sides rough and unequal for attachment of ligaments; on the inner side are two articular surfaces; the upper, large and concave, connected with the trapezoides; the lower, narrow and plane, for the metacarpal bone of the fore-finger.

The trapezoides (*multangulum minus*, Alb.) is very irregular in figure, placed like a wedge between the last and the following bones, the base of it being posterior, the point towards the palm. The upper surface is concave, quadrilateral, and articulated with the scaphoides; the lower divided by a convex line crossing from before backwards, adapted to the hollow of the metacarpal bone of the fore-finger; the dorsal or posterior, convex, rough and broad; the anterior possessing the former characters, but much smaller; the external, convex articulated with the trapezium; the internal or ulnar, smaller and concave, smooth anteriorly where articulated with the following bone, rough behind for ligamentous attachments.

The os magnum (*capitatum*, Alb.) is the largest of the eight; longest in its vertical axis, rounded into an articular head above, (from whence it derives its name,) of a quadrilateral form below. The upper articular surface is convex, divided by a prominent line into two portions, one for the scaphoides, the other for the lunare; the lower is divided into three facets, the external articulated with the second bone of the metacarpus, the middle the largest of the three, concave, supporting the third, the internal or posterior very small, plane, opposed to the inner edge of the fourth; the palmar and dorsal surfaces, rough and unequal for ligaments, the latter the largest of the two, the external narrow, articulated with the trapezoides; the internal of greater extent than any of the preceding, smooth above where contiguous to the unciforme, rough below, giving attachments to ligaments.

The unciforme (*os hamatum*; *cuneiforme* Alb.) completes the second row of carpal bones, being the last on the ulnar side. Above is a rounded angle opposed to the lunare; below a smooth surface, convex transversely, the outer surface supporting the fourth, the inner the fifth metacarpal bone; on the anterior side we observe, below, a curved process projecting forward, to which the annular ligament is attached, as also some muscles of the little finger; it forms the last of the four eminences referred to before; the superior part of this surface is narrow, unequal, but smooth, giving attachment to ligaments; the posterior surface is broad, triangular, and rough; the external offers an articu-

lar surface above, in contact with the os magnum, is rough below for ligamentary connections; the internal is directed obliquely, presenting a curved, oblong, articular facet, and a rough line below it; the former opposed to the cuneiforme, the latter serving for attachments to ligaments.

The bones of the carpus resemble each other in structure; composed of a cellular or spongy substance, externally covered by a thin layer of compact bone. They are developed from single points of ossification, which do not commence till after birth. At that period they are entirely cartilaginous, distinct, well marked, and not at all proportionably larger than when fully ossified, and on this account differing from the cartilaginous extremities of the long bones.

*The articulation of the fore-arm with the carpus, or joint of the wrist.*—The superior surfaces of the scaphoides, lunare, and cuneiforme, form by their union a common convex surface, oblong transversely; each bone is covered by its proper cartilage, firmly united to the next by an intervening band of a fibro-cartilaginous structure, which separates this joint from the articulations of the carpal bones between themselves. The lower extremity of the radius, and the triangular cartilage at the bottom of the ulna, form an elliptical concave surface, which receives the opposite convexity of the carpus, so that the scaphoides and lunare are opposed to the radius, and the cuneiforme to the inter-articular cartilage which separates it from the ulna. The joint is strengthened by ligaments on each side, and also before and behind, and lined by a synovial membrane.

The external lateral ligament is attached above to the styloid process of the radius; it advances forward a little as it descends, and is fixed on the outer side of the scaphoides. The fibres of which it is composed diverge below, and become continuous with the anterior ligament: we can often trace them on to the trapezium. Its form is irregular, and by no means defined, the edges being variously connected with the parts around it. The internal lateral ligament proceeds from the styloid process of the ulna, and is attached below to the inner side of the os cuneiforme. It is implanted also by some of its anterior fibres into the annular ligament, and pisiforme bone.

The anterior ligament is broad, and flat; fixed above to the anterior part of the styloid process of the radius, and the whole anterior edge of the articular cavity; from hence the fibres descend obliquely inwards, and are fixed below in an irregular line to the scaphoides, lunare, and cuneiforme; some fibres go to the pisiforme, the greatest number are attached to the lunare. The flexor tendons lie in front, the synovial membrane immediately behind it. The posterior ligament is not so broad as the preceding, and more evidently fibrous; its direction is nearly the same, being fixed above to the posterior border of the articular hollow of the radius, below the lunare, and cuneiforme; it is covered by the extensor tendons. These ligaments are in no wise connected with the ulna, so that they cannot in any situation impede the rotation of the radius on that bone. The synovial membrane is spread over the articular surfaces of the radius, and triangular cartilage above, and the three bones of the carpus below; it is reflected between them under the ligaments, appearing in the intervals between their fibres in several spots. The joint of the wrist is strengthened on every side by strong and numerous tendons, some of which are inserted in its vicinity, others closely bound to its surface by strong transverse ligaments as they pass from the forearm to the hand and fingers. The security derived from this construction must be very great, without it the joint would presently yield to the many violent impulses it has to sustain

## EXTREMITIES.

sustain, to which the ligaments alone would offer a very inadequate resistance.

*The motions of the carpus on the fore-arm*—are those of flexion, extension, lateral inclinations or abduction, and adduction, and circumduction. From the close connection of the carpal bones between themselves, and with the rest of the hand, these motions of the carpus may be considered at the same time as general motions of the hand. Those of pronation and supination depend on the motions of the bones of the fore-arm, and are in nowise dependant on this joint.

In flexion the articular convexity of the carpus glides from before backwards in the corresponding cavity of the fore-arm, and the posterior ligament and extensor tendons are stretched; it may be carried to nearly a right angle without violence; an effort pressing beyond this point would strain, and might certainly dislocate the bones.

In extension an opposite succession of phenomena occurs, it is the anterior part of the joint which has the effort to sustain. This motion is not confined to the bringing the carpus and hand into the same straight line with the fore-arm, but may be continued in the opposite direction to some extent, so as to make them form a considerable angle with it on the dorsal aspect. The freedom of motion enjoyed by the carpus in this sense is subservient to many of the important uses of the hand, and is not to be found in other analogous joints, where the power of flexion is greater, and that of extension limited to bringing the opposite bones into the same axis, as in the elbow, knee, &c. The lateral motions, those of abduction and adduction, are more confined, especially the last. The lateral ligaments are alternately stretched and relaxed, preventing their too great extent. Circumduction is also confined to narrow bounds, more particularly so when pronation and supination are not concerned in producing it.

*The articulations between the carpal bones*—all communicate together, being lined by a continuous synovial membrane. The bones lie in close apposition, and are bound firmly by ligaments on the palmar and dorsal surfaces, some by ligaments passing deeply between them. The three first bones of the upper row are in contact by nearly plane surfaces covered by cartilage, the scaphoides connected with the lunare, the latter with the cuneiforme. The palmar ligaments uniting them lie deep under the anterior ligament of the wrist, the fibres of each passing transversely from bone to bone. The dorsal ligaments are more distinct, the fibres longer as they are more superficial, they have the same direction as the former. The superior, or interosseous ligaments, have been already mentioned in speaking of the joint of the wrist, as separating it from the articulations of the carpus. They are of close condensed texture, passing between the bones from before backwards, one joining the scaphoides to the lunare, the other this last bone to the cuneiforme. They are very narrow, the upper side smooth, covered by synovial membrane forming a polished surface with the convexity of these bones, with the edges of whose cartilages they are continuous. The os pisiforme is placed without the ranks of the carpal bones, and has no communication with the common joint between them. It rests by a slightly concave articular surface on a corresponding convexity of the cuneiforme; the joint is lined by a synovial membrane reflected from one to the other, strengthened by scattered ligamentous fibres. Two bands of these, of considerable size and strength, pass from the lower side of the bone, one to the root of the metacarpal bone of the little finger; the other to the os unciforme. The pisiform bone is retained in its situation by these, and, in some measure, also by the abductor muscle of the little finger, to

which it gives attachment. Above we observe some ligamentous fibres passing from it to the ulna, and the insertion of the flexor carpi ulnaris. It performs the office of a patella, or sesamoid bone, for this latter muscle "positum porrectumque inter ejus tendinem, ligamentumque ad os metacarpi digiti auricularis pertinens." Its motions are very limited; it forms, together with its connections above and below, a large portion of the channel through which the flexor tendons glide.

To form the articulation between the first and second row we find the scaphoides touching the trapezium and trapezoides, forming, in conjunction with the lunare, a cavity for the reception of the head of the os magnum, and the cuneiform bone supporting the unciforme. The respective articular surfaces are covered by a thin crust of cartilage, and preserved in their situations by palmar, dorsal, and lateral ligaments. The palmar ligaments are short and strong, formed by fibrous bands, passing from one row to the other in different directions; the most superficial are confounded with the anterior ligament of the wrist. The dorsal ligaments resemble them in their passing from the upper row to the lower, but are too irregular in size and direction to allow of specific descriptions. Indeed they are both so mixed with the surrounding ligamentous fibres as scarcely to admit of distinction. Of the lateral ligaments, the external is the shortest and strongest, passing from the scaphoides to the trapezium; the internal stretched between the cuneiforme and unciforme.

The bones of the second row are in contact by cartilaginous surfaces, and connected by ligaments, as those of the first. The dorsal transverse ligaments, are very distinct, one between every two corresponding bones; the palmar are not so well defined, the fibres of each being shorter and more numerous, as they are more deeply seated. We can observe one band, passing from the trapezium to the os magnum in front of the trapezoides, independent of those between the contiguous bones. Between the unciforme and os magnum is a strong collection of fibres passing from side to side through the depth of the carpus, adhering firmly to such parts of the corresponding bones as are not covered by cartilage. A similar connection exists also between the os magnum and unciforme.

The synovial membrane is continued from one articular facet to another, lining the ligaments we have described, appearing in many places between their fibres. Nor does it form a continued surface only between the carpal bones, it is extended below into the joints, between the carpus and metacarpus; not always, however, into those formed above by the os magnum and unciforme. Owing to this general communication, disease of one articular surface is presently propagated to the whole; in this respect it must be considered only as a single joint.

The pisiform bone is in nowise concerned in the mechanism of the carpus; its uses have been mentioned above. So closely are the bones of each row bound one to another, that they allow of scarcely any perceptible gliding motion. The articulations between the two rows allow of a more sensible movement; though this is confined to narrow limits. It resembles somewhat that observed in the joint of the wrist; they can be bent, and extended a little on each other, as well as inclined laterally; the first of these is the most evident. The little motion they possess is produced principally by the articulation of the head of the os magnum, which has the greatest effort to sustain, and has been sometimes luxated backwards. Notwithstanding the obscurity of movement in the carpal bones, it co-operates in increasing the mobility of the hand, whilst at the same time, by the num-

## EXTREMITIES.

ber of articulating surfaces, impulses may be to a certain degree weakened.

Before we enter on the latter point, it will be proper to take some notice of another ligament, materially affecting the solidity of the carpus, though destined but in a secondary way for this purpose, its first office being to confine the flexor tendons in their passage to the fingers. The annular ligament in front of the wrist, (*ligamentum armillare*, *ligamentum carpi proprium*,) passes from the eminences formed by the pisiform and-unciform bones to the opposite ones of the scaphoides and trapezium, completing the canal for the flexor tendons. It is composed of very strong and thick fibres, becoming gradually thinner above and below; rough superficially, lined behind by a synovial bursa. It gives attachment to several muscles of the thumb and little finger. The fibres are all transverse, numerous and compact, securing, in addition to its other uses, the arch formed by the carpal bones. The carpus then derives its firmness from the large surface of the articulating facets in comparison with the smallness of the bones, from their number, from the numerous ligaments, and from the arched form resulting from the connection of the whole. It is further strengthened by numerous tendons, the flexors in front, the extensors on its dorsal surface. Another cause of the solidity of the carpus is, that the articulations between the two ranks are not in the same transverse line, the unciforme, and more especially the head of the os magnum, mounting far beyond the level of the trapezium and trapezoides, so that any impulse would not act on all at once, and cause a general displacement, the effort and the injury must be partial, confined to the articulations between one or two of the bones.

The *metacarpus* (*die mittelhand*, Germ.) - is composed of five bones, resting on the carpus above, giving support to the thumb and four fingers below. They are strong, those supporting the fingers parallel to each other, the other a little anterior, and capable of altering its position. The intervals between them are filled by muscles so as to form a broad and solid body. The anterior face of the metacarpus is concave, constituting the palm of the hand, the posterior convex, and forms the back. The bones are distinguished, from the connections below, into the metacarpal bones of the thumb, the fore, the middle, the ring, and the little fingers, or we class them numerically, beginning on the radial side with the metacarpal bone supporting the thumb. Of these divisions we shall adopt the latter. The first metacarpal is the largest, and shortest of the whole; the second and third are nearly of the same length; the fourth and fifth are successively shorter and smaller. They are all somewhat concave before, and flat behind, presenting several more or less acute angles; larger at each extremity, the upper angular and unequal, the lower forming a convex head, compressed laterally, with an articular surface terminating on the palmar side in two prominent points; smallest in the middle of the body of the bone, increasing gradually in size above and below. In considering the distinguishing characters of each metacarpal bone, we shall observe them as seen on the carpal extremities, the bodies, and the digital extremities of each successively, and not tire the reader by a separate description of the several bones, in which it would be impossible to avoid repetition, and which must necessarily be of greater length.

At the upper or carpal end of the first metacarpal bone we observe an articular surface convex transversely, slightly concave in the opposite direction, opposed to the trapezium. It is surrounded by ligaments, and gives attachment on the outer side to the extensor ossis metacarpi pollicis.

In the second are three articular surfaces, the middle

concave, corresponding to the prominence of the trapezoides; the external small and flat, articulated with the trapezium; the internal divided into two portions, the upper articulated with the os magnum, the lower with the following bone. The circumference of this extremity is rough, and gives attachment to ligaments. On the palmar side is a rough spot, which gives attachment to the flexor carpi radialis; on the dorsal a tubercle, into which the extensor carpi radialis longior is inserted.

In the third a quadrilateral articular surface opposite to the os magnum, bounded before and behind by inequalities, giving attachments to ligaments; on the outside by a smooth facet articulated with the preceding bone; on the inside by two small round articular surfaces, separated by a hollow contiguous to the following bone. At the external dorsal angle is a pyramidal eminence (*processus styloformis*), and close on the inner side the insertion of the extensor carpi radialis brevior.

In the fourth, at the top, a double articular surface, accommodated to those of the os magnum and unciforme, surrounded before and behind by rough points for ligamentous attachments, on the outside by two prominent articular facets, corresponding to those of the last bone; on the inside by a slightly concave surface articulated with the following.

In the fifth, a broad articular surface, convex from before backwards, concave transversely; slanting outwards and upwards, opposed to the unciforme, bounded before and behind by rough surfaces for ligaments, on the outside by a small articular facet connected with the last bone on the inside by a tubercle which gives attachment to the tendon of the extensor carpi ulnaris.

The bodies of the metacarpal bones are all concave anteriorly, and slightly convex on their dorsal surface. Although rather irregular in figure we can distinguish in them four sides, an anterior, a posterior, an internal, and external. In the first the posterior surface is broad; in the three next we observe above a prominent line running lengthwise, which soon bifurcates, forming the lateral boundaries of a flat triangular surface, the breadth of which increases as it approaches the digital extremity; in the last an angular line, running diagonally from the inner side of its carpal end to the outside of its lower extremity. In all of them the posterior surface is covered by the extensor tendons.

The anterior or palmar surface presents also a longitudinal rising line, generally more prominent towards the lower end. It separates the attachments of the interossei muscles, and has somewhat different directions in the several bones. In the first rounded, covered by the opponens, and flexor brevis pollicis; in the third giving attachment above to the latter muscle, below to the adductor pollicis. The lateral surfaces of these bones are broad, inclined obliquely in various directions, giving attachment to muscles. In the first they are compressed and rounded, the outer side giving attachment to the opponens, the inner to the first external interosseus (the abductor indicis of Albinus). In the last the inner or ulnar side gives attachment to the adductor ossis metacarpi minimi digiti; the outer side, as well both sides of the other metacarpal bones, give attachment to and are covered by the external and internal interosseous muscles.

The digital extremities are in all convex, and nearly alike in figure. On the palmar side of the first we observe two slight depressions corresponding to the sesamoid bones in front of the joint; on the sides of the articular surfaces of each deep hollows for ligaments, which secure the articulations between these bones and the fingers.

The metacarpal bones resemble in structure and formation

## EXTREMITIES.

the other long bones. At the period of birth the extremities are cartilaginous, ossification commencing in the body of the bone in the embryo of three months.

In the preceding description we have reckoned five metacarpal bones, according to the plan followed by the most eminent anatomists. By many the first metacarpal bone has been omitted, and described as the first bone of the thumb, which they consider as composed of three bones, like the fingers. By Albinus the metacarpus is divided into two portions, one, comprising the four last bones, he calls the metacarpus manus; the other, the metacarpus pollicis.

The articulations between the bones of the carpus and metacarpus are nearly similar in all but the first. The articular surface at the upper end of the metacarpal bone of the thumb is convex and concave in opposite directions, adapted to the corresponding surface of the trapezium. The joint is surrounded by ligamentous fibres passing from one bone to another, amongst which the external and dorsal are the most strongly marked, and the most in number, the internal and anterior are continued on to the annular ligament. It is lined by a distinct synovial membrane. The disposition of the ligamentous fibres is such as to form a capsule round the articulation, like that observed in the shoulder joint, but not so loose. The whole is supported by the muscles and tendons of the thumb. The second metacarpal bone is articulated with the trapezium, the trapezoides, and the os magnum; the third with the latter only; the fourth with it and the unciforme; the fifth with the last alone. The surfaces are covered by cartilages continuous with those forming the joints between the metacarpal bones themselves, and lined by a common synovial membrane with occasional exceptions, as mentioned when speaking of the carpus. The ligaments on the dorsal surface pass in different directions from the lower row of carpal bones, to the upper end of those of the metacarpus. There are two for the second of these, one from the trapezium, the other from the trapezoides; the third has but one from the os magnum; the fourth two, passing from this bone and the unciforme; the fifth a single band from the latter. They are all short, flat, and compact. The palmar ligaments are less distinct, being confounded with those around them. The most evident are, a band passing from the trapezium to the third and fourth metacarpals, confining in its passage the tendon of the flexor carpi radialis; and a band between the trapezium and first metacarpal.

*The articulations of the metacarpal bones between themselves.*—The metacarpal bones, with the exception of the first, touch at both ends by lateral articular facets, which have been already described. The synovial membrane lining those at the carpal extremity is open above, forming a free communication with the carpus. They are secured in their relations by transverse ligaments at both ends. At the carpal end these are found on the palmar and dorsal surfaces; on the first of these the superficial ligaments form a continued layer, passing from the second to the last, the more deeply seated passing from bone to bone. The dorsal ligaments pass across between each bone. Besides these, we find immediately below the articulations strong ligaments passing deeply between the bones, uniting them most firmly together. At the digital end is a strong transverse ligament on the palmar side, the superficial fibres passing from the first bone to the last, those more deeply seated between each individual bone. It is covered in front by tendons and vessels, behind it supports the interossei muscles, and is united to the ligaments connecting the metacarpus with the fingers.

Among the bones of the metacarpus, the first enjoys very extensive motions in every direction. The most important

motion is that which brings the thumb in opposition to the fingers, and enables us to grasp the object before us; an office which made Albinus bestow on it the emphatic name of “*manus parva majori adjutrix.*” The freedom of this motion depends on the extent and obliquity of the articular surfaces, between it and the trapezium, and is favoured also by their being on a plane anterior to the rest of the hand.

Circumduction of the thumb is very free towards the palm, very much less so in the opposite direction. The interval between this and the other metacarpal bones is highly advantageous in allowing of all its motions. The four last bones of the metacarpus are bound so closely together, as to allow of much individual motion. They can be brought closer together below, and bent a little forwards, so as to increase the hollow of the hand; this motion is most evident in the two last, those of the ring, and little fingers. The four last bones of the metacarpus hold a middle rank, as to motion and solidity, between the carpus and fingers; above they partake of the firmness of the carpus, below approach nearer the mobility of the fingers.

*The fingers, including the thumb,*—are five in number. They are either reckoned numerically from the radial to the ulnar side, or distinguished by proper names. The latter are in common acceptation. We count, therefore, the thumb as the first; the fore-finger or index as the second; the middle finger as the third; the ring finger as the fourth; and the little finger as the fifth. By this arrangement we can immediately compare their relations to the metacarpal bones, which have been described also in a similar numerical order. The fingers are composed of rows of long bones, placed vertically one beyond another, called *phalanges*; of these we find three in the fingers, properly so called, and two only in the thumb, the middle phalanx being wanting. They are distinguished by the names of the first or metacarpal phalanx, the second or middle, and the third or unguinal. As the corresponding bones of the several rows are essentially alike in all, we shall include them in one description, noticing the peculiarities of each. We divide them into two extremities, and a body.

*The first, or metacarpal phalanges,*—are the largest, and longest of the three; of different lengths and size, the third being the longest, and all diminishing successively in volume from the first to the last. They are convex on the dorsal surface, the transverse convexity forming nearly half a circle; concave anteriorly, with sharp angular edges laterally. At the superior extremity we observe an articular surface, oblong transversely, slightly hollowed, articulated with the corresponding bone of the metacarpus; a broad tubercle on each side giving attachment to lateral ligaments, divided anteriorly by a depression, in which the flexor tendons pass. In the thumb this extremity gives attachment to the abductor, the flexor brevis, and the adductor. The bodies of the phalanges are convex posteriorly, covered by the extensor tendons; concave on the palmar side with projecting edges, so as to form a kind of gutter, in which the flexor tendons are partly lodged; the edges give attachment to ligamentous sheaths confining the tendons in their situation. The lower extremity offers an articular pulley, extended further and much broader on the palmar side than on the opposite, and the edges diverging considerably from behind forwards. On each side are depressions, which give attachment to lateral ligaments.

*The second, or middle phalanges,*—are smaller and shorter than the first, which they resemble much in general figure. The thumb possesses none. As to individual comparison, they differ but little, that of the middle finger is the longest, the last belonging to the little finger the shortest and

## EXTREMITIES.

smallest. The upper extremity offers an articular surface crossed antero-posteriorly by a rising line, corresponding to the opposite pulley of the first phalanx; on each side are tubercles giving attachment to ligaments. The body resembles that of the metacarpal phalanx. About the middle of the anterior surface are two rough prominences, giving attachment to the divided tendon of the flexor sublimis, and to a fibrous sheath, which crosses over it from side to side, confining also the tendon of the flexor profundus. Its posterior surface gives attachment to a portion of the tendon of the extensor communis. The lower extremity resembles that of the first.

*The third, or ungual phalanges*—are found, in all, five, diminishing in size from the thumb to the little finger, that of the former being by far the largest of the whole. The upper extremity or base (from a comparison of the bone to a pyramid with its apex downwards), forms an articular surface, oval transversely, with a convex line crossing from before backwards, accommodated to the pulley of the middle phalanx; is tuberculated for ligaments on each side, giving attachment behind to extensor tendons. The body is contracted; on its anterior surface the flexor profundus is fixed in the fingers, and flexor longus in the thumb. The lower extremity, or point, is flat, rounded, broader than the body, scabrous at the edges and on the anterior side, smoother behind, where it supports the nail.

The bones of the fingers have nothing peculiar in structure or formation: the first and second phalanges are formed from three ossifying points, the third from only two. At the time of birth, their figure is well marked, and their formation very considerably advanced.

*The articulations of the thumb and fingers with the metacarpus.*—The convex heads of the metacarpal bones are covered by articular cartilages, in contact with those lining the concave surfaces of the first digital phalanx. They are bound together by lateral ligaments, and strengthened in front by the sheaths of the flexor tendons, behind by the expansion of the extensors, on each side by the interossei muscles. The lateral ligaments are attached above to the sides of the lower end of the metacarpal bones, and divide as they descend into two distinct bands, which are fixed to the sides of the corresponding bones of the first phalanx. They are strong, formed of parallel fibres, lined on the inner surface by the synovial membrane. In front of the joint we find the transverse ligament of the lower end of the metacarpus, which has been already described. The synovial membrane is loose, particularly before lining the extensor tendon in its passage behind over the joint, and appearing between the ligaments, which it also covers in front and on the sides. In front of the joint of the thumb we find two sesamoid bones developed in the tendons of the flexor brevis, leaving a furrow between them, in which the tendon of the flexor longus passes. They rest on the head of the metacarpal bone, gliding up or down, as the joint is bent or extended. They are sometimes found in the articulations between the metacarpus and fingers. The motions enjoyed by this joint are those of flexion, extension, abduction, and adduction; of these the first is by far the most considerable, the thumb possessing it in the least, the little finger in the most extensive degree.

The articulations between the phalanges are alike in all; the condyles, at the lower extremities of the first and second phalanx, are covered by cartilage, and correspond to the little hollows at the upper ends of the second and third. They are covered by a synovial membrane, and connected by lateral ligaments, which pass from bone to bone, resembling those of the preceding articulation. The synovial

membrane is supported by these, as also by the extensor and flexor tendons. It is so closely united to the extensor tendon, at the upper end of the second and third phalanx, that it is almost impossible to separate them. It is continued much further down on the bone on the palmar, than on the dorsal surface, forming a little bag in front of the joint. The thumb has but one of these articulations, which is in every respect similar to the joints between the phalanges of the fingers.

In this last part of the hand we observe an evident decrease of firmness, when compared with the metacarpus and carpus, and a proportionate increase of facility and extent of motion. The shortness of the bones, however, scarcely offering a resisting point to external impulses; secures their relations, and lessens the chance of fracture, though the fingers are more immediately within the action of surrounding bodies, and more exposed to injuries than any other part of the limb. The joints of the phalanges of the thumb and fingers allow only of flexion and extension; the latter cannot be carried beyond the straight line, the former is very free; an effect which depends on the continuation of the articular surfaces in front, far beyond their extent on the dorsal surface, and which is provided for by a corresponding laxity of the synovial membrane. The advantages of this disposition, for the important functions of the fingers, is so conspicuous as to require no comment. In opening the hand, the fingers cannot be extended beyond the plane of the hand; from this situation they may be bent in various degrees, until their points touch the lower end of the metacarpus. This general flexibility, derived from the successive rows of firm bones, and their peculiar modes of articulation, allows of the fingers being applied accurately to any body whose qualities we wish to examine, whatever be its figure. The decreasing length and size of the several phalanges permit us to seize objects conveniently and firmly; to retain them, however small. The power we possess of moving them singly, or in different degrees, of touching the palm of the hand at any point of its surface, of spreading them laterally, of separating one from another, &c. enables us to adapt their position to every possible use. In all the actions of the hand, the thumb holds a conspicuous rank. Alone, it opposes the efforts of the other fingers; which are much longer, and bend, as it were, to meet the thumb, whenever we close them on the object. With regard to the different lengths of the thumb, and several fingers, we may observe, that when separated most widely from each other, by gently bending the points they may be brought to describe nearly a circle on a plane surface, forming with the hollow of the palm a concave hemisphere; from which situation they may be further contracted, till the several points meet: from this construction they are suited to grasp equably and firmly bodies of a rounded form. The sense of touch owes, in a great measure, its delicacy and perfection to the readiness and precision with which the fingers can be applied to the object whose qualities we wish to examine. It would be almost endless to describe the different motions of which they are susceptible; they are so rapid in succession, so varied in direction, extent, and power, so exquisitely adapted to the innumerable offices they have to perform, as to constitute an inexhaustible, not to say an inexplicable subject for discussion.

We conclude our history of the upper extremity, by some remarks on its powers of resistance and susceptibility of motion, as a complete member, enjoying the assemblage of all the properties we have described as resulting from the mechanism of each division.

The cases in which the upper extremities are required to support

## EXTREMITIES.

support great efforts, or to oppose a powerful impulse, are by no means so numerous or so frequent as in the lower limbs, where considerable exertion and resistance are necessary, to support the body in the ordinary attitudes. In the action of pushing, the hand is applied to an object, the fore-arm and arm extended between it and the trunk forming a straight lever, which conveys the weight of the latter on the body to be pushed. In this motion the hand being inflected backwards on the fore-arm, the joint of the wrist is soon fatigued by the distension and pressure in front; the sigmoid cavity of the ulna bears directly against the lower end of the humerus, the latter rests on the glenoid cavity of the scapula, which is fixed firmly by its muscles and the clavicle.

It is only, however, when the arm is directed outwards, that it bears directly on the glenoid cavity; if it be turned forwards or backwards, the capsular ligament and the surrounding muscles sustain the effort. The first circumstance is most favourable to firmness and continued resistance; and we may observe, that when at liberty to choose our attitude in pushing with one arm, we always place it in such a direction as to bring it to bear directly on that cavity. For instance, if the object be in front, we turn ourselves so as to bring the side of the body corresponding to the limb we are about to exert opposite to the object. In pressing downwards, in resting on the arm, &c. the mechanism is nearly the same, as far as regards the hand, which is so much extended on the fore-arm as to form an angle with it behind, while the fore-arm is placed in the same line with the arm, the joint of the elbow being fixed and immovable. The difference depends only on the change of situation which takes place in the joint of the shoulder, the head of the humerus pressing more or less advantageously, as the direction of the pressure varies from the relative position of the object on which the limb rests.

The best possible direction is where the arm is extended laterally, so as to bear on the glenoid cavity, the scapula being at the same time supported directly by the clavicle. It is understood that in every case the position of the limb is preserved by muscles, which are called on to act more or less, as that position is more or less favourable for sustaining the effort, and become tired in the same proportion. This observation is more particularly applicable to the case in which the upper extremities have to sustain the whole weight of the body, as in the instance of tumblers, when the hands are placed on the ground, and the body raised into the air, the upper exerting for a time the functions of the lower extremities. This attitude is both difficult and painful, from the want of sufficient muscles to maintain it, and from the small extent of the articular surfaces. The wrist suffers more particularly, as in marching on all-fours, because these surfaces do not bear on each other, but on the front of the joint; the elbow is not so much distended from the construction of the articulation; the shoulder-joint suffers almost equally with the wrist, from the pressure on its capsule. The upper extremities are articulated with the trunk in a plane posterior to the lower; the line of gravity in the attitude above-described is anterior to the support, and we find, consequently, that to preserve the balance, to counteract the tendency to fall forwards, the lower extremities are thrown considerably backwards.

The motions of the upper extremity are so numerous and varied, as scarcely to admit of classification; they are so familiar as not to require description. The mechanism by which they are performed has been considered in treating of the several articulations, and may readily be applied to any case; we shall now only briefly recapitulate the more mate-

rial points. The shoulder is the centre of motion of the whole limb; the arm gives the general movement, the parts below those which are more partial. The motions of the shoulder affect the whole limb; as we descend, the actions are more and more confined. A finger may be employed while the arm is motionless; if the latter is moved, all below must partake of the motion. It is from the combination of the several partial motions that the increase and variety of the whole are derived, and these are multiplied the lower we go. The hand enjoys the individual motions of its component parts; a general motion from the joint of the wrist; a more general still from the connection of the bones of the fore-arm and the elbow, which is increased to a still greater extent by the shoulder joint and shoulder. The motions then may be more compound as we descend, as well as more partial, because each part enjoys the motion resulting from its proper articulation, in conjunction with all those above it. This general action of the parts of the upper extremity is observable in seizing or grasping any body, or in embracing, where all the articulations are bent, or in the opposite actions of spreading the arms, or extending the whole limb in different directions, &c. It is more commonly seen under cases where the different joints are inflected variously at the same time, some extended, and others bent, these motions being often alternate. All these modifications of action may be observed in pushing, pulling, climbing, grasping a distant object, swimming, striking, &c. &c. In short, in all the familiar exercises of the upper extremity we are constantly in the habit of performing. We cannot conclude without hinting at those impressive actions of the upper extremity, which form a mute language employed most emphatically in aiding the expressions of our passions, or our will; it is enough to say, they are as numerous and varied as the feelings which bring them into play.

*The lower extremity*—is divided, as the upper, into four parts, viz. the hip, the thigh, the leg, and the foot, each of which has a more or less striking analogy with the corresponding divisions of the upper extremity. We shall examine their points of resemblance and difference more minutely hereafter; at present, we would observe only, that the bones, which form the basis of the lower extremity, are more massy and solid in their forms, and are hence adapted to their functions, as organs by which the rest of the body is supported and moved. Their prominent character is solidity and firmness; in the upper extremity every thing is constructed for variety and quickness of motion.

The lower extremity is connected with the trunk by the articulation of the hip bone with the basis of the vertebral column, the sacrum; through which the whole weight of the body is transmitted to the bones of the hip. The connections of the two hip bones with the sacrum behind, and with each other in front, form a bony cavity called the *pelvis*, the principal uses of which are, to contain some important viscera, to offer a basis of support to the trunk above, and two fixed points for the motions of the limbs below. It is in the last functions only that we shall have occasion to notice the pelvis here; we shall not, therefore, enter into a description of it as a whole; but attend to those of its parts which bear on the present subject, and correspond to analogous portions of the upper extremity.

The *os coxae*, *os innominatum*, hip, or haunch bone, is the largest of the broad bones, placed laterally at the lower end of the trunk, connected with its fellow in front, by means of cartilage, and separated from the opposite bone behind by the intervention of the sacrum. The hip-bone is very irregular in figure, broad and flattened above, con-

## EXTREMITIES.

tracted and massy in the middle, and apparently more slender in the anterior and lower portions: it is curved so as to have its flat surfaces in almost opposite directions; the upper division is flattened from side to side, the lower from back to front, the change of direction taking place in the middle portion. In young subjects this bone is formed of three separate pieces; a superior, called the *ilium*, an anterior, the *pubes*, and an inferior, the *ischium*. In the adult they are so intimately united, that we can with difficulty trace their former line of separation. We can see therefore no reason for describing as distinct, what in its perfect state forms but one solid bone. We shall consider it as such; but, not to deviate too much from common usage, shall notice the different divisions as we proceed, and afterwards particularly describe their lines of union. We distinguish in the *os innominatum* two surfaces; an internal or pelvic, an external or femoral, and a circumference or border, which is again subdivided into several parts.

The external surface looks outward above, and forwards below; it is covered by strong and numerous muscles. The outside of the broad upper division, the dorsum of the *ilium*, is convex and concave in different parts; at the posterior and superior part is a rough eminence, which gives attachment to the *gluteus maximus*; below this a surface, concave and broad behind, convex and gradually narrowing in front, gives attachment to the fibres of the *gluteus medius*; it is bounded by the eminence just mentioned, by the upper edge or crista of the *ilium*, and below by a semi-circular line, with the convexity upwards, passing forwards from a deep notch behind, (the great sacrociatic,) and terminating in the crista of the *ilium* in front. The space comprised between this curved line and the deep articular cavity below, gives origin to the *gluteus minimus*; it is concave behind, and gibbous in front. At the anterior part, immediately above this cavity, is a rough impression, where the curved tendon of the *rectus cruris* is fixed. The portion of the external surface, which is directed downwards and forwards, is very irregular in figure. Above is a deep and large cavity, called the *acetabulum* or cotyloid cavity; it forms nearly the half of a sphere, lined by cartilage in its upper two thirds, the lower part a little deeper, lodging some cellular tissue, and the strong ligament passing to the head of the thigh-bone. The margin of the cavity is irregular and waving, more prominent above than below, surmounted by a ligamentous ring, which makes the *acetabulum* still deeper, interrupted towards the inner side by a notch, completed by a ligament which leaves only a small opening for the passage of the articular vessels; it gives attachment to the capsular ligament of the hip joint. The bone surrounding the cotyloid cavity is thick and massy, especially at the upper and outer sides; the cavity itself is directed obliquely outwards, downwards, and forwards. Below, and on the inner side of this cavity, is a large hole, of an oval shape, the *foramen ovale*, *obturatorium*, or *thyroideum*. Its long diameter is from above downwards, its edges are acute and rough, except at the upper part, where there is a smooth gutter directed obliquely from above inwards and downwards, in which the obturator nerve and vessels are lodged. The groove is formed by the internal and external edges of the circumference crossing each other at the top of the oval, the latter passing in front to a point called the spine of the *pubes*, leaving the oblique hollow between itself and the internal margin which passes up in the opposite direction. The *foramen ovale* is closed by a ligament attached to its edges every where but at the groove just mentioned, where it leaves a vacancy for the passage of the obturator vessels, &c. In the female this foramen is smaller than in the male,

and of a triangular figure. On the inner side of the foramen is a rough and unequal surface, broader above and below than in the middle, giving attachment to portions of the *triceps*, and the external obturator muscle.

The internal or pelvic surface is concave, corresponding in its direction to the external or femoral, covered by muscles which arise from it. The anterior part of the upper division, the *fossa iliaca*, is occupied by the *iliacus internus* muscle; the posterior is very scabrous and unequal, divided into two portions, of which the anterior is covered by cartilage, and articulated with the sacrum, forming the *sacroiliac symphysis*, resembling somewhat in outline the human ear, the posterior is convex and very rough, giving attachment to the strong and numerous ligamentous fibres which connect this bone with the sacrum above. Below the *iliac fossa*, crossing from the articular surface to the anterior angle of the bone, is a prominent angular line, forming a part of the superior aperture of the pelvis, separating the upper division from the lower. The latter presents a plane surface behind, broader above than below, giving attachment to the *obturators internus* and *levator ani*; in front of this is the *obturators foramen*, and in the inside of the latter a narrower surface corresponding to the bladder above, giving origin to a part of the *obturators internus* below.

The circumference of the *os innominatum* is exceedingly irregular, with alternate prominences and hollows, and is divided into four portions, *viz.* a superior, an inferior, a posterior, and an anterior. The superior margin bears the name of the crista of the *ilium*; is convex, narrower in the middle than at the ends, and inclined outwards. The inner edge, or *labium*, gives attachment to the *transversalis abdominis*, and *quadratus lumborum*; the external to the *obliquus externus*, the *latissimus dorsi*, and the *fascia of the thigh*; the middle convex portion to the *obliquus internus*. The anterior margin is concave, and its lower half nearly horizontal. Its union with the crista forms the anterior superior spine of the *ilium*, which gives attachment to the *tenor vaginæ femoris*, the  *Sartorius*, and the upper end of that part of the tendon of the external oblique, called *Poupart's ligament*. Below this point is a slight notch, rising again into another eminence, the anterior inferior spine of the *ilium*, from which the *rectus cruris* arises. This is succeeded by a smooth hollow, over which pass the *psaos magnus*, and *iliacus*, bounded by a protuberance called *eminencia ileo-peetinea*, into which the tendon of the *psaos parvus* is implanted, when it exists. On the inside of this there is an oblique surface, concave, triangular, with the base outwards, and the point inwards, bounded in front by a line which is continued from the external margin of the *obturators foramen*, behind by a sharp ridge, the crista of the *pubes*, which is continued from the transverse line described as crossing the pelvic surface. Over this concave space pass the crural vessels. The anterior margin terminates by uniting with the inferior, at a right angle, called the angle of the *pubes*. A little before its end we observe on it a projecting point, the spine of the *pubes*, giving attachment to the *pyramidalis*, and the external pillar of the abdominal ring, formed by the tendon of the external oblique. The inferior margin is the shortest, presenting above a perpendicular oblong surface, forming with the opposite bone, by the intervention of cartilage, the *symphysis pubis*; below this the edge is thinner, forming with the opposite one the arch of the *pubis*, affording attachment to the *gracilis*, to portions of the *triceps*, to the *corpus cavernosum*, the *transversalis perinei*, and the *erector penis*, or *clitoridis*. The upper half of this bony plate is called the descending ramus of the *pubis*, the lower the ascending ramus

## EXTREMITIES.

mus of the ischium. The posterior margin is the most irregular in its outline. Beginning from above we observe the angle formed by its junction with the superior margin, the superior posterior spine of the ilium, an hollow separating it from the eminence below, the inferior posterior spine; a very deep notch forming part of the sacro-sciatic notch; a sharp prominence, the spine of the ischium, giving attachment to the superior gemellus, the coccygeus, and the lesser sacro-sciatic ligament; a smooth concave surface, over which the tendon of the obturator internus plays; and a broad eminence where it joins the inferior margin, the tuberosity of the ischium giving attachment, externally, to the quadratus femoris, and the great head of the triceps; within to the great sacro-sciatic ligament, and the inferior gemellus, in the interspace to the biceps, the semi-tendinosus, and semi-membranosus.

The os innominatum is in structure like the other flat bones; the two compact tables, enclosing the more cellular parts, touch each other in the middle of the iliac fossa, and again at the depression in the acetabulum. It is developed from three points of ossification, at the angle of the pubis, the tuberosity of the ischium, and the middle of the upper division, or ilium. The union of the bony plates proceeding from these points takes place between the ilium and pubes at the eminentia ileo-pectinea; between the latter and the ischium, in the middle of the branch which forms the inner side of the foramen ovale, and the half of the arch of the pubes; between the ischium and the ilium at the great sacro-sciatic notch. The junction of the three takes place in the acetabulum, which forms the principal point of union; the ilium makes the upper part of the cavity, the pubes the anterior, the ischium contributing the principal share, and completing it at the inferior and posterior portions. The part which either bone takes in forming any of the principal features of the os innominatum will be immediately seen, by observing their lines of union with each other. At the time of birth the acetabulum, being far removed from the centres of ossification, is wholly cartilaginous, as are also the different eminences, the spines, and the cristæ. It is not till the time of puberty that all traces of cartilage are obliterated. The os innominatum is articulated with the sacrum, by the sacro-iliac symphysis; with its fellow, by the symphysis pubis; and with the thigh-bone by means of the cotyloid cavity. We shall say nothing of the two former of these connections, but that they are exceedingly strong, and the bones bound so closely together, as not to allow of any perceptible motion; we shall describe the last after having gone through the history of the thigh bone.

In commenting on the mechanism of the shoulder, we had to notice its articulation with the trunk, and the motions resulting from its peculiar mode of connection; in the present instance we find an immoveable adherence of surfaces, which allows of no deviation from one determined position. In consequence of this total want of motion, we shall not enter on the detail of the connections of the hip bone with the trunk, or with its fellow; they can influence the functions of the lower extremity no farther than by transmitting to it the weight of the body.

The oblique direction of the articular surfaces of the sacrum, which gives it the form of a wedge driven between the two ossa innominata, is well adapted to the purpose of transmitting securely the weight of the trunk to the latter bones: the stronger the depressing impulse, the more closely the surfaces are brought together; the shock must be violent indeed, which can in anywise loosen their connection. It is then through the medium of the sacrum that every effort is propagated to the two hip

bones, which in some positions are the immediate base of support, while in others they continue the impulse to the limb below. In the common attitude of sitting, the trunk is supported on the tuberosities of the ischia; in progression, or in standing, on the cotyloid cavities. These being at a distance from each other, facilitate the motions of the thighs, and increase their extent, the pubes executing one of the offices of the clavicle, in keeping the hip joints far asunder, as the clavicle does those of the shoulder. It will be seen, from the description of the hip bone, that its surfaces and circumference give attachment to numerous and powerful muscles, by far the greater number of which are destined to regulate, or to give vigour and effect to the motions of the thigh and leg, and to balance the varying weight above them.

*The thigh*—is the division of the lower extremity between the hip and the leg. It is formed by a single bone, called the *femur*, or *thigh bone*.

The femur is the longest bone of the body, the largest in volume, and the strongest. It has a considerable curve forwards, is contracted in the middle, wider and more bulky at each extremity, one of which is called the upper, or *iliac*, the other the lower, or *tibial*.

The upper extremity includes three remarkable eminences; the head, supported by a long neck, and the great and little trochanters. The rounded head of the femur is received into the cotyloid cavity of the os innominatum; it forms more than half of a sphere, directed upwards, inwards, and a little forwards; so that the greatest part of its convexity is above, and its axis the same as that of the neck, which sustains it. The convex surface is smooth, except just below the centre, where we find an hollow, which gives attachment to an inter-articular ligament; it extends further in front than behind, above than below, and terminates in a waving line at the neck. The latter contracts immediately below the head, and becomes a little flattened vertically, the upper edge remaining the widest; it is longer below and behind, on which aspects it is also hollowed, than above and in front; joined by a broad basis to the body of the bone, from which it stands off in a direction slanting upwards and inwards, advancing at the same time a little forwards, forming with it an angle more or less obtuse. The length and obliquity of the neck vary considerably in different subjects, being in some nearly horizontal. The great trochanter is on the outer side, directed a little backwards, below the level of the head, rising above the hollow of the neck, quadrilateral, convex on the outside, and excessively rough for the attachment of strong tendons, the tendon of the gluteus maximus passing over the smooth surface at the posterior part; hollow, and of much less extent on the inside, giving attachment above to the tendons of the gemelli, the obturator internus, and the pyramidalis below, and towards the back part to the obturator internus. It has rough and irregular borders; to the anterior is fixed the tendon of the gluteus minimus; to the lower part of the posterior the quadratus; to the upper the gluteus medius; to the lower the vastus externus. The attachments of these muscles are hardly, however, confined to the edges of the trochanter; their tendons are implanted also to a greater or less extent over the outer surface, for which purpose its roughness, as mentioned above, seems particularly designed. The little trochanter is placed at the internal and posterior part of the base of the neck, oblong and somewhat pyramidal in shape, its rough summit giving attachment to the united tendon of the psoas magnus and iliacus. From its base we trace two prominent lines proceeding obliquely upwards to the great trochanter, one uniting them

## EXTREMITIES.

them in front, the other behind. These, in conjunction with the two trochanters, mark the circumference of the basis of the neck, and give attachment, more especially the anterior, to the capsular ligament of the hip joint. The body of the thigh bone is convex forwards, and hollowed behind, appearing nearly cylindrical when viewed in front, but almost triangular above, and flattened transversely towards the lower end. It has been divided in descriptions into three surfaces and as many angular lines; these characters, however, are not strongly marked; the surfaces are universally smooth, the dividing lines blunt and rounded, if we except the posterior ridge formed by the union of the internal and external surfaces, called with great propriety the *linea aspera*, or *spina femoris*. This is formed by two converging rough lines, commencing from each trochanter above; that which proceeds from the trochanter major is the most prominent and rough, giving attachment to the *gluteus maximus*; the *pectineus* is affixed to the other; and the interspace is occupied by the *quadratus* and a portion of the *triceps*. The double ridge, formed by the approach of the two rough lines, is continued down the bone, when it again divides into two less remarkable lines, which terminate in the condyles at the lower extremity. The whole middle of the *linea aspera* gives attachment to the *triceps*; a portion of the *biceps* has its origin at the lower part, which is continued along the line diverging towards the external condyle; the line going to the internal condyle is scarcely observable for a little way below the point of bifurcation. These two branches of the *linea aspera* leave a triangular interval between them, smooth and somewhat concave, corresponding to the popliteal vessels. Besides the muscles fixed to different parts of the *linea aspera*, the *vastus externus* is attached to almost the whole extent of the line, proceeding from the great trochanter to the external condyle; and the *vastus internus* is connected in a similar manner to the line from the little trochanter to the internal condyle. The surfaces of the body of the femur are covered by these muscles, and by the *crureus*, which cover the bone at every point, excepting towards the lower end, and the space intercepted between the bifurcation of the *linea aspera*. The nutrient arteries of the body of the bone are found in the course of the *linea aspera*; the principal one about the point of convergence above.

The lower extremity much exceeds the upper in volume, and presents two eminences called condyles, the internal and external. They are both convex, project more behind than in front, are smooth below for articulation with the tibia, this surface being terminated behind by two hollows, which give origin to the heads of the *gastrocnemius*. They diverge behind, leaving a deep notch between them, where the crucial ligaments of the knee joint are fixed; on the front they are joined by a continued articular surface, which is hollowed to receive the knee-pan or patella; the edge of the pulley formed by the outer condyle being more elevated than the opposite one. The articular surface terminates abruptly in the lateral direction, in the perpendicular rough sides of the condyles; in front it is continued a little way up the bone, ending in a slightly prominent edge. The internal condyle gives attachment on the inner side to a lateral ligament, and to the tendon of the *triceps*. The external surface of the outer condyle is marked by a depression to which the *popliteus* is affixed, and by an eminence for the external lateral ligament of the knee. The articular surface of this condyle is broader than that of the internal, and not so convex, the anterior part being nearly plane; and it is continued much higher up in the front than on the opposite side. The internal condyle, when the

thigh bone is placed perpendicularly, appears to descend much lower than the external; but in the natural oblique direction of the femur, the bottom of the two condyles will be found nearly in the same horizontal plane, the internal still exceeding a little.

The femur is compact in its structure in the middle part, reticular and spongy at the extremities, which are yet cartilaginous at the time of birth. Ossification commences in the middle of the bone, and it is not till after this has reached the extremities that we observe three centres of ossification above, in the great, the little trochanter, and the middle of the head, and two below, one for each condyle. The cartilages between them and the body of the bone gradually decrease in thickness, and they become united, the two trochanters the first, then the head, and last of all the conjoined condyle. It is not till the bone has nearly arrived at its complete and adult form that the line of separation is entirely obliterated. In infancy the neck of the bone is nearer at right angles to the body than at any after period; as the age advances the angle becomes more and more obtuse in the majority of subjects; in some few it scarcely alters its direction. This alteration, from an horizontal to an oblique line, is a proof among many others how little the functions or growth of the animal body are subject to physical laws; we see the neck of the thigh bone rising, as it were, in direct opposition to the weight of the super-incumbent body. This portion of the femur is also proportionally shorter than in the adult, and wholly cartilaginous. The body of the bone is straight, instead of being curved forwards, as in the adult; and the inferior extremity is comparatively of larger dimensions. These characters of the infantile bone are lost as it gradually becomes developed, and acquires its remarkable density and firmness. The thigh bone is articulated above with the *os innominatum*, below with the tibia and patella.

*The articulation of the femur with the os innominatum, the hip joint.*—The surface of the cotyloid cavity of the hip bone is lined by an articular cartilage, of which the central parts are thinner than the circumference. It terminates at the edge of the depression observed at the inner and lower parts of the cavity, which is filled up by a fatty cellular tissue, supplied by numerous vessels. The bony margin of the cavity is completed by a ligament crossing the notch, and the whole rim of the acetabulum is surmounted by a circular ligament, called the cotyloid ligament; which much increases its depth. In this round articular cup, or acetabulum, the head of the thigh bone is lodged. The latter is covered by cartilage thinner at the circumference than towards the centre, where it is partially interrupted by the insertion of a ligament, and accommodated exactly to the opposite surface of the acetabulum; the cartilaginous head, however, is so deep as not to be wholly embraced by this cavity in any position; and hence some part of its margin always appears exposed on turning back the enveloping ligament. The contiguous surfaces are secured in their relations by a very strong capsular ligament, supported by fibres from the neighbouring parts, and surrounded on all sides by muscles; and by an inter-articular ligament. The opposed surfaces are covered by a synovial membrane.

The cotyloid ligament adheres firmly to the edge of the acetabulum at every point, excepting the great notch which it crosses. It is thick at the border next the bone, thin at the opposite prominent margin, broader above, and externally thin in the contrary directions, and partially broader wherever there is any depression in the osseous rim, so that the unconnected margin of the ligament is exactly plane throughout. It is formed by ligamentous fibres arising from

## EXTREMITIES.

from the edges of the cavity without, inclining gently towards it in their progress, and inserted again into the sides of the margin within at a greater or less distance from their point of origin. These fibres receive an addition above from the curved tendon of the *rectus cruris*; below they are confounded with the fibres of another ligament, completing the great notch. The latter is formed by two cross planes of fibres passing from one edge to the other; they decussate each other in their course, one band corresponding to the surface of the joint, the other to the edge of the obturator foramen, from the ligament occupying which it partly takes its origin. They leave a vacancy below for the passage of vessels into the joint; towards the brim of the cavity they are continuous with the cotyloid ligament in the manner above-mentioned; they give a partial attachment also to the ligamentous capsule. The cotyloid ligament, in conjunction with these bands, completes the figure of the acetabulum, and by increasing its depth secures the joint without in any degree diminishing the motions of the head of the femur, to the pressure of which it readily yields. They are both lined towards the joint by the synovial membrane, which is continued over the edge of the cotyloid ligament a little way down the opposite surface, before it is reflected to the capsular ligament. These two last are opposed to each other in part by its intervention; towards their mutual attachment to the brim of the cavity they are intimately united. Into the articular hollow thus constituted, the head of the femur is received, and secured by an orbicular and internal ligament.

The capsular ligament of the hip joint, (*l. orbiculare, membrana capsularis femoris, Soemm.*) extends from the circumference of the acetabulum to the base of the neck of the femur. It is fixed to the bony margin of the former from the line of insertion of the cotyloid ligament, to a short space beyond it, so as to surround the latter, which projects freely into the joint. Its insertion extends further beyond the cotyloid ligament in front and on the outer side than it does internally, where it may be almost said to arise from its very edge. From this circular attachment the capsule descends, enveloping in its course the chief part of the neck of the femur, to the circumference of whose base it is finally fixed. In front it reaches the oblique line between the trochanters, the *linea inter-trochanterica*; behind, some of its fibres only reach so far, the greater number are implanted into the neck between the posterior oblique line and its middle; above, it is fixed to the root of the great trochanter; below, it extends nearly to the little. The capsular ligament is in general very thick, and of a close and condensed texture; it is thinnest internally and behind, thicker externally, and most decidedly so in front, where it is strengthened by a layer of longitudinal fibres arising from the anterior margin of the *os innominatum*, and from the anterior inferior spine, and fixed below to the anterior *linea inter-trochanterica*. In other parts of the ligament the course of the fibres is less distinctly marked; from the margin of the acetabulum they follow different directions, decussating each other, and leaving occasional intervals, more especially below, through which vessels pass to the synovial membrane. This last is occasionally exposed and bare on the side next the obturator foramen. The capsular ligament is covered in front by the *rectus cruris*, *psoas magnus*, and *iliacus internus*, a synovial bursa lying between them; on the internal side, by the *obturator externus* and *pectineus*; behind, by the *quadratus femoris*, the gemelli, the tendon of the *obturator internus*, and the *pyramidalis*; above and without, by the *gluteus minimus*, which is more closely connected with it than any other of these muscles.

The interior, or round ligament, (*ligamentum teres, internum*) is entitled to almost any name rather than round; it is flattened, and of a triangular figure, the base towards the acetabulum, the summit next the head of the femur. It is fixed at one end to the extremities or corners of the great notch of the cotyloid cavity, and to the posterior edge of the transverse ligament occupying the vacancy; from thence it mounts obliquely backwards, and is attached to the depression noticed towards the centre of the head of the thigh bone. It appears as if composed of two bands of fibres, one arising from the superior, the other from the inferior extremity of the great cotyloid notch, which approach each other towards their opposite insertion. The upper of these is by far the weakest; in many cases it appears only as a duplicature of the synovial membrane, enclosing only a small number of ligamentous fibres. It must restrain the head of the femur from quitting the cavity upwards and outwards, and must be partially, if not entirely, ruptured in the luxations in those directions; in the displacement towards the obturator foramen it would not apparently suffer much injury.

The synovial membrane lines the cotyloid cavity, is spread over the fatty cellular tissue, occupying the sinus at its bottom, is reflected from thence over the internal ligament, which it wholly encases, adhering to it more or less intimately in different parts: it covers the articular cartilage of the head of the femur, is continued over the periosteum of the neck, which appears through it as if formed of parallel fibres; at the base of the neck it turns back over the inner surface of the capsular ligament, lines it to its attachment round the brim of the acetabulum, and from thence passes over the cotyloid ligament. The hip joint is very much strengthened by the surrounding muscles, especially by those which immediately cover it.

The motions which take place in the hip joint resemble those in the shoulder; they are, however, with the exception of rotation, less extensive, owing to the immobility of the cotyloid cavity, its great depth, and the comparative tightness of its capsular ligament. The femur can be bent on the hip bone, extended, brought nearer to, or removed further from, the mesial plane, moved between these directions, or carried round in a circular direction (*circumduction*), and rolled inwards and outwards. In the most common position, with the thigh in the same line as the body, the summit of the great trochanter, which can be always felt externally under the integuments, is in the same horizontal line with the spine of the pubis, and about the middle of an oblique line extended between the superior anterior spine of the ilium, and the tuberosity of the ischium. By a previous knowledge of the relative position of this eminence to points which can be easily felt, we shall be competent to decide on any accidental displacement, as well as to follow the alteration of position in the different motions of the femur.

When the thigh is bent, the head rolls in the acetabulum in the axis of the neck, the summit of the trochanter recedes from the spine of the ilium, and approaches the tuber of the ischium, and the lower end of the bone is advanced. In moderate flexion there is but little alteration in the relations of the articular surfaces; when carried to its greatest degree, a portion of the head of the femur quits the acetabulum, and rests on the posterior part of the capsular ligament, which undergoes considerable distension. Extension of the thigh is the replacement of the limb in its former state, from the position of flexion. The very close manner in which the head of the bone is covered in front by the strong ligamentous fibres, which proceed from the anterior and inferior spine

## EXTREMITIES.

of the ilium, and the neighbouring anterior portion of the cotyloid line, entirely prevent us from carrying the limb backwards beyond a perpendicular line drawn from the pelvis downwards, if the latter part be preserved immoveable. The degree of motion in this direction, if it exist at all, is very trifling, supposing the trunk to be erect, and the pelvis fixed; the apparent freedom of motion in the direction of extension arises from the pelvis being ordinarily moved in the opposite direction.

In abduction, or removing the thigh from its fellow, the great trochanter rises towards the fossa of the ilium, which it touches, if the motion be continued as far as possible, and thereby limits the extent of that motion. The internal surface of the head abandons the acetabulum, while the external sinks deeper into it; the capsular ligament is made very tense on the inner side, where it supports the head and opposes its tendency to any displacement in that direction. In adduction nothing remarkable occurs; it is merely the return of the thigh from the last position to its natural one; the limb may, however, be carried, in this direction, across the opposite one. Besides these four motions in opposite lines, it will be readily understood that the femur can be moved through all of the intermediate points. Circumduction is not so free as in the shoulder joint, as may be gathered from the preceding observations: rotation is, on the contrary, less confined, on account of the length and obliquity of the neck of the femur, so strikingly different from that of the humerus. In the latter rotation is nearly in the axis of the bone, on account of the extreme shortness of the neck; in the femur, where the axis of the bone is so far removed from the centre of motion, this motion passes round a line extended from the upper part of the head to the middle point or interval between the condyles. In rotation inwards, which is more confined than that outwards, the great trochanter describes the arc of a circle from behind forwards, and the head of the bone is buried deeper in the cavity; the motion of the trochanter is more sensible and more extensive as the neck is proportionally longer. In rolling the thigh outwards the great trochanter sinks under the muscles, and the head of the bone distends the capsule somewhat in front. In its most natural position the thigh is turned a little outwards, which contributes, with the direction given to the foot by the construction of the ankle joint, to point the toes moderately outwards. As the leg and foot necessarily follow the rolling motions of the thigh, and more perfectly so when the leg is extended on the latter, it will be seen that the rotation of this bone inwards and outwards will imply a corresponding alteration in the position of the foot; and the great power we enjoy of turning the toes outwards, and the narrow limits to which we are confined in directing them inwards, will be found to result from the difference observed in the powers of rotation of the thigh.

The motions of the hip bone on the thigh, when the latter is the fixed point, will require no particular detail after the preceding remarks. It is sufficient to say they may be made in every direction, and with tolerable facility, particularly lateral inclination, in which one hip bone is lowered, and the opposite one elevated, and rotation; motions executed with promptness and to a great extent in the *pirouettes* of our stage dancers. We shall have occasion to speak at length of the flexion and extension of the hip bones on the thigh, when we examine the mechanism of the whole in the attitude of standing.

*The leg*—is the part of the lower extremity placed between the thigh and the foot; the bones which it contains are the tibia, the fibula, and the patella.

The tibia, the largest of the three, alone supports the weight placed on the leg from above; it comes next to the femur in size, is larger above than below, nearly triangular throughout, divided into an upper, femoral extremity, or head, a middle part or body, and a lower or tarsal extremity.

The upper extremity is nearly oval, with the long diameter transverse, large, and spreading.

The vertex or top presents two articular hollows or sinuses; of which the internal is oblong from before backwards, and deeper than the external, which is nearly circular. They correspond to the condyles of the femur by the intervention of moveable cartilages; and are divided from each other by a middle eminence, terminating in a rough depression before and behind, which completes the separation. This protuberance, placed nearest to the posterior edge of the head, is not much elevated; it slopes into the articular surfaces at the base, and is bifid at the summit, with a rough groove in the interval. The rough depression in front is larger than that behind; they both give attachment to the semi-lunar inter-articular cartilages of the knee, and to the crucial ligaments of the joint. In front of the upper extremity is a broad, flat, triangular surface, with the base upwards, corresponding to the ligament of the patella. The lateral parts have been called the tuberosities; they project considerably by a convex edge, separated in front by the flat space just mentioned, behind by a notch varying much in depth. The internal protuberance is the largest, and is marked by the attachment of the semi-membranosus behind, the external presents in the same aspect a rounded articular surface inclined downwards, for connection with the fibula.

The body of the tibia is slightly curved outwards above, and inwards below, diminishing in bulk as we trace it from the upper extremity till about one-third from its lower end, from which point its size gradually increases again downwards. It is of a prismatic form, with strongly marked edges. The anterior of these, the crista or spine, commences above at a rough eminence, called the anterior tuberosity of the tibia, into which the inferior ligament of the patella is fixed in front, and the tendons of the sartorius, gracilis, and semi-tendinosus internally; it is sharp above and in the middle, in the latter of which portions it projects a little, and becomes insensibly lost below; it forms by its course a waving line, which gives attachment to the aponeurosis enveloping the muscles of the leg. The internal edge is flattened above, and more angular below; in the first portion it gives attachment to the popliteus, for the lower two-thirds to the long flexor of the toes. To the external ridge, the least prominent of the three, the interosseous ligament is fixed; below it bifurcates and is continued into the edges of the articular cavity, which receives the lower end of the fibula. Of the surfaces between these edges, the internal or the shin is the largest; smooth, slightly convex above, and covered by the tendons of the sartorius, gracilis, and semi-tendinosus; throughout the rest of its extent it lies immediately under the skin. The outer surface is hollowed longitudinally above, and convex below, where it turns a little forward; its upper half is covered by the tibialis anticus, to which it gives attachment, and lower down the tendon of this muscle, with those of the extensor of the great toe, and the common long extensor of the toes, pass over it. The posterior surface is crossed obliquely by a line passing downwards and inwards from the articular surface, at the back of the external tuberosity; above this the popliteus is attached; below, the tibialis posticus, and long flexor of the toes; to the line itself these muscles are fixed, as also the soleus. It

## EXTREMITIES.

is towards the upper end of the posterior surface that we find the hole which gives passage to the nutrient vessels.

The lower extremity is much less in volume than the femoral or upper; it is nearly quadrilateral with an articular cavity of the same form at the bottom, which rests on the foot. Of the four sides, the anterior and posterior are straight, transversely and nearly parallel, giving attachment at their edges to ligamentous fibres; the latter presents also a groove for the passage of the long flexor of the great toe. The internal is prolonged downwards below the level of the others, forming a broad and strong process, called the malleolus internus. This eminence does not correspond exactly to the inner tuberosity of the femoral end, but is situated a little more forwards from the slightly twisted form of the bone. The circumference of its anterior and lowest parts gives attachment to ligaments; the posterior has a broad and superficial hollow, over which pass the tendons of the tibialis anticus, and the long flexor of the toes; the inner surface is convex, and covered by the skin, the external is smooth, presenting a vertical articular surface, joining above the large articular cavity, the depth of which it considerably increases. On the outer side of the tarsal extremity is a triangular hollow with the summit upwards, smooth below, and covered by cartilage, where it receives the fibula, rough above for the attachment of strong and short ligamentous fibres, which secure the connection: the edges of the cavity are continued above into the external spine of the body of the bone, and give attachment to ligaments which pass to the fibula. The articular surface at the bottom is a little concave, quadrilateral, narrowest and deepest towards the inner side, crossed antero-posteriorly by a broad gently rising eminence; it corresponds to the upper surface of the astragalus, the highest of the bones of the tarsus.

The structure and formation of the tibia resemble those of the other long bones. At birth the extremities are cartilaginous, and are not completely ossified and united to the body till a late period; the bony spines in the latter are already very prominent, and better marked than in any other bone. The tibia is articulated with the femur, the fibula, and astragalus.

The patella, rotula, or knee-pan (kniescheibe, Germ.) is situated in front of the knee-joint, or articulation between the femur and tibia, varying as the leg is bent or extended, in its relative position with regard to the femur. It is flattened, of a triangular form, with the base upwards, the upper angles rounded, the lower more acute. The anterior surface is convex, pierced by numerous longitudinal openings, covered by a tendinous expansion from the extensors of the leg, which is partially attached to it, and by the skin. The posterior articular surface is oblong, transversely divided by a blunt elevated line, passing rather obliquely from the upper edge to the lower angle, into two differently inclined concave faces, of which the external is the largest and deepest; they both correspond to the condyles of the femur on which they play. It is terminated below by a rough depression, into which a portion of the ligament of this bone is fixed. Of its circumference, the upper edge is thick, and gives attachment to the tendon of the extensors, the lateral borders slightly convex, to the common aponeurosis of these muscles. In the lower angle the strong anterior ligament which connects the patella to the tuber in front of the tibia is firmly implanted.

The substance of the patella is spongy in the middle, covered by a thin crust of compact bone. It is formed in the thickness of the tendon of the extensors, and always preserves the appearance of longitudinal fibres. It is not till some years after birth that bony matter is deposited in room

of the cartilaginous substance at first observable, and it is a later period still before it is fully developed. The patella is articulated with the femur, and connected with the tibia by means of a ligament, of which we shall speak below.

*The knee joint, or articulation of the femur with the tibia and patella.*—This joint, one of the most complicated in the body, results from the contact of the condyles of the thigh bone with the head of the tibia and the posterior surface of the patella. The first of these, as well as the articular pulley formed by their union in front, are covered by cartilage, which is thicker in the middle of the condyles than at their circumference; the cartilage covering the patella is particularly thick, it is thinner on the hollows of the tibia, particularly in their centres. The forms of the articular surfaces of the femur are accommodated to those of the patella and tibia; but in the latter case the correspondence is further maintained by means of two inter-articular femi-lunar fibro-cartilages, interposed between the femur and tibia in such a manner, that a small portion only of the latter bone comes into actual contact with the condyles of the former. The relations between these parts are secured by muscles, and their tendons, by the ligament of the patella, two lateral, and the same number of crucial or oblique ligaments, a posterior ligament, and by a synovial membrane spread over the whole.

The ligament of the patella, which may be regarded as the termination of the tendons of the extensor muscles, consists of a very strong flat band of fibres attached above to the lower angle of that bone, and to the depression on its posterior surface, from which points it extends about two inches in length, and half as much in breadth to the anterior tuberosity of the tibia. It is covered in front by the skin and an aponeurotic expansion. The posterior surface corresponds above to some fat and cellular tissue lying betwixt it and the synovial membrane, below to a small synovial capsule placed between it and the tibia, a smooth portion of which it covers, just above the insertion of the ligament. The edges are continuous, with an aponeurosis proceeding laterally to the tibia. It is composed of parallel, shining, tendinous fibres, of which the anterior or most superficial are continued in front of the patella to be identified with those of the immediate tendons of the extensors. It is exceedingly strong, and capable of resisting the strongest efforts of these muscles.

The internal lateral ligament is flat and thin, attached above to the internal condyle of the femur, it becomes broader as it descends, part of its fibres is inserted into the edge of the internal semi-lunar cartilage, and into the edge of the head of the tibia, the greater portion contracted in breadth is continued further down, and becomes fixed at the commencement of the body of the bone to the internal edge, where it joins the aponeurotic insertion of the popliteus. It is covered by an aponeurosis descending from the fascia lata of the thigh, and below by the tendons of the sartorius, the gracilis, and semi-tendinosus: it lies over the synovial membrane, the internal semi-lunar cartilage, and a small part of the tibia. The external lateral ligament is placed between the external condyle of the femur, and the fibula, in the form of a long, round, shining cord, covered nearly throughout by the tendons of the biceps. Immediately under it are the inferior articular vessels. It is fixed to the condyle above the attachment of the tendon of the popliteus, and rather behind it; to the fibula on the outside of its upper extremity, adhering to the outer semi-lunar cartilage in its passage. The posterior ligament is nothing but a tendinous expansion given off from the tendon of the semi-membranosus, which mounts obliquely up-

## EXTREMITIES.

wards and outwards behind the crucial ligaments, from which it is separated by cellular tissue and the middle articular vessels. It is attached above to the external condyle, and is confounded with the tendon of the outer head of the gastrocnemius. Independent of this band, which is very irregular in its form and size, we find other fibrous parcels crossing in different directions above it.

The crucial ligaments are more deeply seated, but may still be considered as external to the joint as they are covered only in front, and on the sides by the synovial membrane, and are really without the sac which it forms. They are strong fibrous bands crossing each other in their course, from which they derive their name. The anterior passes from the posterior and upper part of the hollow between the condyles, and from the interior side of the external condyle; obliquely downwards and forwards, narrowing as it descends, to be fixed in the rough surface, in front of the spine at the head of the tibia, behind the attachment of the internal semi-lunar cartilage, and on the inside of the external; being partially united to both. The posterior crucial ligament is attached above to the anterior part of the sinus between the condyles, and the outer-side of the internal condyle. It descends backwards and inwards, becomes broader, and divides into two pretty distinct bands, of which the largest is inserted into the depression behind the spine, the other joins the external semi-lunar cartilage. These two ligaments are separated from each other by cellular tissue, and by the same means from the posterior ligament behind; they adhere firmly to the synovial membrane, investing them on the anterior and lateral surfaces.

The semi-lunar cartilages, as they are termed, lie on the articular surfaces of the tibia, between them and the corresponding condyles, occupying only the circumference, the femur and tibia touching in the centre of each. They are thick at the convex margin, and become gradually thinner, terminating in a delicate concave edge, increasing thereby the depth of the cavities which receive the gibbous condyles of the femur. The internal is broadest behind, the external in front; the first represents a portion of an oval, of which the short diameter is transverse; the latter forms nearly a circle, corresponding, in this respect, to the figure of the two articular surfaces of the tibia. The upper surface of each cartilage is concave, accommodated to the convexity of the condyles, the lower is nearly flat. The convex margins are united to the ligaments which cross them in their course, especially to the lateral; that of the external has an oblique depression in it behind, where it is contiguous but not adherent to the tendon of the popliteus. The concave edges are free, thin, and sharp. The anterior extremity of the internal cartilage passes in front of the anterior crucial ligament, and is inserted on the outer side of the depression which gives attachment to it; the posterior is attached behind the spine, before the insertion of the posterior crucial ligament. The anterior extremity of the external semi-lunar cartilage is fastened to the depression in front of the spine, but much behind the attachment of the internal, and united in part with the anterior crucial ligament; behind it is implanted into the posterior depression, and is connected with a portion of the posterior crucial ligament. We have called these cartilages, not to depart too much from established language, though they are of a fibrous texture. They are formed of curved concentric fibres, which are particularly evident at their extremities and convex margins, less so in the middle, where they are more analogous in their appearance to cartilage. They are sometimes immediately joined by a short transverse ligament, continued from the convex borders in front. The internal appears more fixed in its

situation than the external, which has a gliding motion backwards and forwards on the tibia.

The synovial membrane, if we trace it from above, is reflected from the condyles of the femur, some way above the termination of the cartilage to the circumference of the patella. In this part it is loose, covered above by loose fat and by the cruræus, to the tendon of which it adheres most firmly, and laterally by an aponeurotic expansion, from the extensors passing from the edges of the patella to the tibia and femur. After lining the posterior surface of the patella, it passes on to the upper edge of the tibia in front, lying under the ligament of the former bone, and a large quantity of fat and cellular tissue placed underneath it, and keeping them at a considerable distance. From this part a duplicature of it passes backwards through the joint, and is attached to the anterior and external part of the sinus between the condyles. It has been called the ligamentum alare by Weitbrecht, or *l. mucosum*, seu *adipolum*; all names equally unapplicable to it. Laterally, also, it descends towards the tibia, investing the upper surfaces, and concave edge, and the under surfaces of the semi-lunar cartilages; after which it is continued downwards, covers the articular cartilages at the head of the bone, and is reflected upwards over the crucial ligaments in the middle, lying behind the tendons of the gastrocnemius on their anterior surface, and enveloping the tendon of the popliteus. It thus reaches the condyles behind, to the edges of which it is attached, leaving the sinus between them without the bag, and passes over the cartilages to the point from which we set out. It is covered in front by the extensors and their tendon; by their aponeurosis laterally, as also on the inside by the tendons of the  *Sartorius*, *gracilis*, and *semi-tendinosus*, and by the internal lateral ligament with which it is in contact; on the outside by the tendon of the biceps and the external lateral ligament, behind by the semi-membranosus and its lateral tendon, by the gastrocnemius and popliteus. After all, we should have a very imperfect idea of the knee joint, if we considered it in this abstract state. It is most strongly supported by the muscular powers attached to the tendons we have mentioned, the latter being numerous, and of great strength, and the muscles massy and exceedingly powerful, securing most effectually, when in action, the relations of the opposite bones.

*The motions of the leg on the thigh*—are those of flexion, extension, and under particular circumstances of rotation. In flexion, the tibia and semi-lunar cartilages glide backwards on the condyles of the femur; the patella quits the articular pulley, and descends in front of the joint, so as to be opposite to the sinus between the condyles: the tendon of the extensors occupies its place, and is much distended if the flexion be carried far back, as is also the ligament of the patella; and the crucial and oblique ligaments, as well as the posterior, are relaxed. In extension, the tibia glides forwards again, and the semi-lunar cartilages are brought opposite to the inferior instead of the posterior surfaces of the condyles, which, in this position, rest against the heads of the gastrocnemius; the patella mounts again, and, in complete extension, if the muscles are in action, passes up a little way above the articular pulley; if the muscles are quiescent, the tendon of the patella is relaxed; this bone is loose and may be moved in all directions; the posterior crucial and lateral ligaments are stretched, and prevent this motion from being carried beyond the point which brings the femur and tibia in the same line. The great strength of the crucial ligaments, which are essentially distended at this time, is a powerful obstacle to the luxation, which would throw the head of the tibia backward. When the leg is near the middle state,  
between

## EXTREMITIES.

between complete flexion and extension, it can be rotated slightly inwards and outwards; a motion, of which the foot necessarily partakes, and which carries the toes in corresponding directions. In rotation the articular surfaces of the tibia glide in opposite curves in the rounded surfaces of the condyles; not, however, in equal degrees, the most evident motion occurring on the outer condyle. In rotation inwards the posterior crucial ligament is brought to cross the anterior more directly, and is much tightened, so as effectually to limit it. In rotation outwards, which, on account of the disposition of these ligaments, is more extensive, we find them scarcely affected. In both cases the lateral ligaments are rendered tense; the semi-lunar cartilages undergo little change of position, excepting that in rotation inwards, the external one, from its connection with the posterior crucial ligament, is drawn a little aside. When the leg is bent, the motions by which the toes are carried alternately inwards or outwards take place in the knee joint; when it is extended, they are effected in the hip, and depend on the rotation of the femur. The patella favours extension, by removing the power further from the centre of motion, besides which it glides more readily over the pulley of the femur, than a flexible tendon could have done, and protects materially the front of the joint in flexion, for instance in kneeling. It scarcely moves in rotation inwards or outwards.

*The fibula*—is placed on the external side of the leg, obliquely with regard to the tibia, being behind it above, and immediately on the outside below. It is a slender bone, nearly equal in length to the tibia, but very much smaller, divided into an upper or tibial, or lower or tarsal extremity, and a middle portion or body.

The upper extremity is very irregular; we remark in it above, and a little on the inside, an oblique, slightly hollowed, articular surface, corresponding to one on the outer tuberosity of the head of the tibia. In every other aspect the surface is rough and unequal, giving attachment to ligaments which connect it with the tibia, to the external lateral ligament of the knee, and to the tendon of the biceps.

The body of the fibula is of an irregular prismatic figure, somewhat twisted, and curved a little, so as to approach nearer the tibia in the middle of the three angles, the anterior rises gradually from above, is sharp and prominent in the middle, and bifurcates below, where it is covered only by the skin. It gives origin, in the greatest part of its extent, to an aponeurosis, which separates the peronei muscles from the extensor communis of the toes. The external edge is spiral in its course, running backwards as it descends. It gives attachment to an aponeurosis, which divides the peronei from the long flexor of the great toe and the soleus. The internal edge becomes anterior as it descends; it is very prominent in the middle, and gradually lost above and below. The upper two-thirds give origin to the flexor of the great toe, and the tibialis posticus, the lower third to the interosseous ligament. Of the surfaces between these borders, the external alters its aspect, becoming posterior below; it is covered by the peronei, which are fixed to the two upper thirds. The internal surface looks rather backwards above, and forwards below; it is divided into two unequal portions by a spine extending from the upper part of the anterior angle to the lower part of the internal angle, and which gives attachment to the interosseous ligament. Of these two planes the anterior is covered by, and gives origin to, the extensors of the great and of the other toes, and to the peroneus tertius; the posterior, which is hollowed longitudinally, to the tibialis posticus. The direction of this

spine varies very considerably, as also its length. The posterior face is inclined outwards above, where the soleus has its attachment; below it turns inwards, giving attachment by nearly its lower two-thirds to the long flexor of the great toe. About the middle is the opening for the nutrient artery directed longitudinally downwards. It widens towards the lower extremity, where it terminates in a rough convex surface, connected with the tibia.

The lower or tarsal end of the fibula is oblong, flattened transversely, thicker behind than in front; it forms the outer malleolus, which descends rather lower, and is more pointed than the inner. The external surface is convex, and covered only by skin; the internal presents, at its anterior part, a smooth articular surface convex from above downwards, articulated with the external side of the astragalus, and behind this a rough depression for ligamentous attachments. The posterior border has in it a superficial groove for the passage of the peronei; the anterior, as well as the angle below, give attachment to ligaments.

The fibula is in structure like the other long bones. It is formed from three points of ossification, one for the body and one for each extremity. The latter are still cartilaginous at birth.

*The articulation between the tibia and fibula*—is by actual contact at the two extremities, and by means of an interosseous ligament in the intervening space. The superior articulation results from the contact of two flat cartilaginous surfaces, secured by ligaments in front and behind, and covered by synovial membrane. The anterior ligament passes from the fore part of the upper end of the fibula to the anterior part of the external tuberosity of the tibia. The fibres are transverse, the superior ones the longest, and divided into several parcels, with intervening cellular tissue. It is strengthened by a portion of the tendon of the biceps, which embraces the external lateral ligament of the knee, and passes over this anterior ligament before it is fixed to the tibia. The posterior ligament is also transverse, but not so strong, or so well marked as the preceding; it is continued above with some ligamentous fibres found in the back of the knee-joint; it is covered by the popliteus. Besides these two ligaments, we find a few other scattered bands below, which help to secure the articulation. The synovial membrane lines these ligaments, and the cartilaginous surfaces; it is separated from the tendon of the biceps by cellular tissue, and is contiguous behind to the synovial membrane of the knee. The middle connection is preserved by means of an interosseous ligament, analogous to the one we have described in the forearm. It is thin, composed of parallel fibres descending obliquely from the external edge of the tibia to the ridge dividing the internal surface of the fibula, and below to the internal edge of this bone. It is broadest at the upper part, and terminates in a point beneath, where the bones begin to touch each other. It is pierced by many openings for the passage of vessels; of these the most remarkable are, one above, near the edge of the fibula, for the passage of the anterior tibial vessels; and another below for a branch from the peroneal artery. The anterior surface serves for attachment to the tibialis anticus, the extensors of the great and other toes, and to the peroneus tertius, and supports the anterior tibial vessels. To the posterior surface the tibialis posticus and long flexor of the great toe are fixed. The inferior articulation is composed of the contact of two cartilaginous surfaces below, a convex for the fibula, and a corresponding concave one for the tibia, lined by a continuation of the synovial membrane from the ankle joint. The relations are secured by ligaments before, behind, and between

## EXTREMITIES.

tween the bones. The anterior ligament is broad, attached to the anterior edge of the tarsal end of the fibula; in crossing to the tibia it mounts a little upwards, widening in its progress, its fibres divided by intervals filled with cellular tissue, the superior the longest, and is fixed to the neighbouring parts of the tibia. It is covered by the peroneus tertius, aponeurosis of the leg and the shin; its lower end is confounded with ligamentous fibres passing from the fibula to the astragalus. The posterior ligament resembles it in direction, but it is not so large, and the lowermost fibres are the longest. It passes immediately from the posterior part of this end of the fibula to be fixed to the tibia behind the cavity which lodges that bone, is confounded with the surrounding ligaments below, covered behind by the two lateral peronei muscles. In addition to these ligaments we observe, between the opposite surfaces of the two bones, just above their cartilaginous contact, a fibrous substance passing from one to the other, occupying a considerable space, interrupted here and there by cellular tissue, and continuous above with the interosseous ligament. It materially secures the articulation.

The motions of the fibula on the tibia are excessively limited, very different in this respect from those between the bones of the fore-arm. The upper end of the fibula may glide a little backwards and forwards; the lower is nearly motionless from the disposition of the ligaments, a structure necessary for the stability of the articulation of the leg with the foot, as resisting the tendency to lateral displacement.

*The foot*—forms the last division of the lower extremity; it has some characters in common with the hand, but is distinguished from it in a remarkable manner by its great depth and firmness, by the preponderance of its solid over its moveable parts, the reverse of which is so strikingly seen in the hand. It varies much in size, in general is proportionally smaller in the female than in the male, is elongated in form, broad and flat anteriorly, thick and narrower behind. It is convex on the upper surface, which is called the back of the foot, concave on the lower, called the sole, thin on the outer edge, deeper and longer internally, with a projection behind, named the heel, and terminated by the points of the toes in front. We divide it, as we did the hand, into three portions; the tarsus behind, the metatarsus in the middle, and the toes before.

The tarsus (oberfuss, Germ.) forms about the posterior half of the foot; it is composed of seven bones, viz. the astragalus, the os calcis, naviculare, cuboides, and three cuneiform bones.

The astragalus, (talus of Albinus,) occupies the upper part of the tarsus, rising far above the level of the other bones; it is of a very irregular form, convex above, hollowed below, flattened at the sides, and running out into a strong process before, termed the cervix or neck of the bone. It is placed fast between the two bones of the leg, the heel bone, and the os naviculare. On the upper surface, anteriorly, is a rough, transverse depression, forming part of what has been called the neck of the bone, for insertion of ligaments; behind this is a large articular surface, broader before than behind, convex in those directions, rather concave from side to side, so as to form a superficial pulley, suited to the opposite surface of the tibia. Below we have two articular surfaces, which rest on the os calcis, separated by a deep groove, running obliquely from within outwards, widening much in its course, and rough for ligamentous attachments. The posterior articular surface, which is external, is the largest, concave, and oblong obliquely; the anterior is small, oval, and nearly flat. The

posterior side is narrowed horizontally, and presents the commencement of an oblique groove, in which the tendon of the long flexor of the great toe glides. In front is a convex rounded articular surface, which has been called the head of the bone; it rests against the os naviculare, and by a small surface on the os calcis. On the outside a triangular articular surface, concave vertically, corresponding to the lower end of the fibula. On the inside another articular surface, flat, elongated horizontally, adapted to the descending malleolus internus; below this a rough irregular surface for ligaments. These two articular surfaces are continuous with that on the upper surface, and form part of the ankle joint. It is developed from two points of ossification, which are just appearing at birth.

The os calcis (calcaneus of Albinus,) is situated at the posterior part of the tarsus, where it forms the heel. It is the largest of the seven bones; its greatest extent is from behind forwards, its next is in the depth, and it is narrowest transversely. On the superior surface we observe posteriorly a concave part occupied by the fat and cellular tissue in front of the tendo Achillis; next we have a large, convex, oblique articular face, adapted to one in the astragalus; on the inside of this a groove, which divides it from another smaller oval, flat, articular facet, corresponding also to the astragalus. This last is placed on a lateral process of the bone, ("sulentaculum cervicis tali, Alb.") and is rather anterior to the first. It is sometimes continuous with another small articular surface in front of it, though generally separated by a narrow groove. The rest of the upper surface is flat and rough for ligaments. The under surface is long, much contracted transversely, terminated behind by two tubercles which give attachment to some muscles of the toes; the internal is the largest. There are also other eminences further in front to which ligaments are fixed. The posterior surface is bulging and convex, and forms properly the heel; at the upper part it is smooth, where it is separated from the tendo Achillis by a synovial bursa, and rough below for its insertion. The anterior surface is the smallest of the whole; it is articulated with the os cuboides, and is slightly concave. The outside is flat, much broader behind than before, and marked by two superficial grooves for the long and short peronei muscles. The inside is large and hollowed deeply, to lodge the nerves and vessels going to the sole of the foot, and also the tendons of the tibialis posterior, the long extensor of the toes, and the long extensor of the great toe, which plays in a peculiar groove observed at its upper part. The musculus accessorius has its origin from this surface, towards the back part. The os calcis is formed from two points of ossification, which are visible at birth. The two bones we have been describing have been considered as the first row of tarsal bones; the remaining five as the second.

The os naviculare is situated in the middle of the tarsus, of an oval figure, with its longest diameter transverse; its circumference is rough for ligamentous attachments; broad and convex above, concave below, pointed and projecting internally where the tibialis posterior is inserted, and narrowed on the outer side, on which we generally find a flat articular facet opposed to the cuboides. The anterior surface is convex, divided into three articular planes for the three cuneiform bones; of these the internal is broadest below, and the two external above. The posterior surface is concave, articulated with the astragalus.

The os cuboides, (cubiforme, Alb.) is placed at the external and anterior part of the tarsus, and resembles somewhat a cube in figure. Above is a rough, slightly convex surface, with four unequal sides; below posteriorly an emi-

## EXTREMITIES.

nence for ligaments, a superficial hollow, and a more marked protuberance for the same purpose, in front of which is a deep groove, which gives passage to the tendon of the peroneus longus, as it crosses the foot. Anteriorly an oblique articular surface nearly plane, supporting the two outer metatarsal bones. Behind a concave smooth surface, still more oblique, articulated with the os calcis. Externally, a narrow border, in which we observe the commencement of the groove for the tendon of the peroneus longus. Internally, a small articular facet behind, in contact with the os naviculare; a larger one in the middle for the third cuneiform bone; the rest of the surface is rough for ligaments.

The first cuneiform bone (*majus five internum*) lies at the inner and anterior part of the tarsus, and is the largest of the three; it is deeper than it is broad, with the base of the wedge below, and the narrower border upwards, of a rhomboid figure viewed laterally. The upper side is oblique, and gives attachment to ligaments; the inferior is convex, and gives attachment before to the *tibialis anticus*, behind to a part of the *tibialis posticus*, as well as to ligaments. The posterior surface, articulated with the naviculare, is concave and pointed above; the anterior, by which it rests on the first metatarsal bone, is longer, and of an oblong, or rather semi-lunar figure. Internally, it is convex, rough, and sub-cutaneous; externally concave, with a small articular facet near the upper edge, in contact with the second bone of the metatarsus, and another near the posterior edge, which touches the following bone.

The second cuneiform bone (*minus five medium*) is the smallest of the three, and of all the bones of the tarsus; it well deserves its name both from its figure and situation. The base of the wedge forms the upper surface which is quadrilateral, with the short diameter transverse, and rough for ligaments. The edge of the wedge below is sharp, and serves the same purposes; behind it is articulated by a concave surface, with the middle plane in the front of the os naviculare; before, by a convex one, with the second metatarsal bone. Of the two four-cornered sides the internal is nearly plane, with an articular facet near the upper edge, and another at the posterior, joined to the last bone; the external has a concave articular facet for connection with the third cuneiform bone towards the upper and posterior angle: they are both rough on the remainder of their surfaces for fibrous attachments.

The third cuneiform bone (*externum, or medium, Alb.*) is rather larger than the preceding, and longer from before backwards; it resembles it much in figure and position. The base, which is above, and the edge below, give attachment to ligaments. Behind is a triangular articular surface, corresponding to one of the planes in front of the naviculare; before an oblong flat one in contact with the third metatarsal bone. The internal surface is marked by two articular facets, separated by a rough depression for ligaments, of which the anterior corresponds to the second metatarsal bone, the posterior to the second cuneiform. The external side is rough anteriorly, and has a plane articular facet towards the upper and posterior angle, in contact with a corresponding one on the inner side of the *euroides*.

The last five bones of the tarsus are wholly cartilaginous at birth, and are gradually and solely developed from single points of ossification. They are not proportionably larger in this state than when in their perfect osseous forms, in which respect they resemble the carpus.

*The articulation of the leg with the foot, the ankle joint.*—To form this joint, the upper articular surface of the *atragalus*,

nearly all the outer side, and the narrow cartilaginous facet on the inside, are received into the cavity formed by the lower end of the tibia and fibula, and embraced closely by the two ankles. The corresponding surfaces are covered by cartilage, and united by several ligaments, the most efficient of which are placed at the sides; the connection is much strengthened by the numerous tendons which pass over or near it to be attached to different bones of the foot.

The internal ligament (*l. deltoides*) is of considerable breadth; attached above to a part of the circumference of the internal malleolus, more especially to its point, it descends a little obliquely backwards, and is fixed to the inner surface of the *atragalus*, and the neighbouring parts of the os calcis. It is composed of a considerable quantity of longitudinal fibres, of which the anterior and the most superficial are the longest. On the inside, the tendon of the *tibialis posticus* passes over it, and is connected with it by its fibrous sheath; it is contiguous also to the long flexor of the toes. On the outside is a straight rounded and thick ligament (*l. medium perpendiculare*) which descends from the lower extremity of the fibula a little obliquely backwards, passing under the tendon of the peroneus longus, and is attached to the outer side of the os calcis; it is formed of compact, longitudinal fibres. In front of this is another ligament (*l. anterior malleoli externi*), which passes from the anterior part of the point of the outer malleolus, forming a strong flat band of fibres, frequently divided into two or more portions of considerable strength, and is fixed to the *atragalus* in a depression before the external articular surface. The front of the joint is strengthened also by a collection of irregular fibrous bands, which descend from the anterior part of the lower extremity of the tibia, amidst much cellular tissue and fat, and are inserted partly into the *atragalus* close to the termination of the articular pulley, and are partly continuous with the ligaments passing from this bone to the naviculare. Towards the back of the joint, we have arising from the fibula a strong ligament (*l. posterius malleoli externi*) passing nearly transversely inwards, and fixed to the edge of the articular pulley at the back of the *atragalus*, close to the outer margin of the groove for the tendon of the long flexor of the great toe. It is stronger than any of the preceding ligaments, and composed of numerous distinct packets of fibres. Immediately above this, and connected intimately with it, at its origin from the back of the external malleolus, is a transverse band of fibres passing directly across, or mounting a little obliquely, to be attached to the posterior border of the articular surface of the tibia, and to the inner ankle. It increases a little the depth of the articular cavity behind, and might be regarded properly as one of the posterior ligaments connecting the tibia and fibula. The synovial membrane is distributed as usual, lining all the cartilaginous surfaces and the ligaments; lining also the narrow articular facets between the tibia and fibula, making this little joint communicate with that between these bones and the *atragalus*. It is loose in front, where we find a considerable quantity of cellular tissue and fat; covered in this aspect by the tendons of the *tibialis anticus*, the long extensors of the great, and other toes, and the peroneus tertius; behind by the tendons of the *tibialis posticus*, the flexors of the toes, and the peronei; partly in these situations, and on the sides by the ligaments just described. In addition to the many tendons enumerated, this articulation is further strengthened by the tendo Achillis behind, a powerful agent in preserving its relations.

The motions which take place between the leg and foot are chiefly those of flexion and extension; the lateral in-

flexions.

## EXTREMITIES.

flexions are extremely limited. In flexion, which is more confined than the opposite motion, on account of the disposition of the articular pulley of the astragalus, this bone glides backwards on the lower end of the tibia, regulated by the two malleoli lying close on either side; the posterior ligament is stretched, the others undergo but little change; and luxation rarely occurs. In extension the motion may be continued, so as to make the foot form a very obtuse angle with the leg; the external anterior ligament is distended considerably, the others less so, the posterior is relaxed. In standing on the toes this position is maintained by muscular efforts, particularly by means of the tendo Achillis; the tibia rests on the posterior part of the pulley of the astragalus, and transmits the principal weight to the naviculare, instead of the os calcis, as in ordinary station. The lateral inclinations of the foot on the leg, as far as this joint only is concerned, are extremely confined, owing to the lateral descent of the malleoli; in which respect they differ much from the lateral motions of the carpus on the fore-arm. The lateral ligaments are here reciprocally stretched or relaxed, as the foot is turned inwards or outwards. Dislocations to either side occur more frequently than we might at first imagine from the apparent security afforded by the malleoli. Luxation outwards is the most frequent, the fibula breaking two or three inches above its lower end, so as to allow of the eversion of the foot; it is generally the consequence of sudden violence, as in jumping, or in falling on the foot from any height.

*The articulations between the bones of the tarsus.*—The astragalus is articulated by two, sometimes three cartilaginous planes on its inferior surface, with corresponding ones on the upper surface of the os calcis. These surfaces are preserved in contact by a strong collection of ligamentous fibres, passing directly upwards from the whole length of the oblique groove, between the articular facets on the upper surface of the os calcis to a similar depression on the under side of the astragalus, where it is attached to every point not occupied by articulating cartilage. The internal fibres lie deep between the bones, and are short; the external ones are longer, and more in quantity, buried in the cellular tissue and fat which contribute to fill the vacancy observed in this part. Behind there are some parallel fibres passing down from the back of the astragalus to the os calcis, which concur in forming the sheath for the tendon of the long flexor of the great toe; they are not numerous. This articulation is also strengthened by the lateral ligaments of the ankle joint, especially by the external, which passes immediately from the fibula to the os calcis. The synovial membranes offer nothing remarkable. The motions which have place here are always combined with others, and will be considered farther on.

The anterior convex articular surface of the astragalus is received into a cavity formed by the concave surface of the os naviculare, a small spot of the os calcis, and completed below by ligaments passing between these two bones. We observe above a dorsal ligament, thin and flat, composed of fibres passing from the depression called the neck of the astragalus to the upper rough surface of the naviculare; they sometimes reach to the cuneiform bones. It is covered by the extensors of the toes. Below is a very strong ligament, passing from the anterior and internal parts of the os calcis obliquely forwards and inwards to be attached to the hollow in the lower surface of the naviculare. It is covered on the inside by the tendon of the tibialis posticus: above it is lined by synovial membrane, and forms the lower part of the cavity which lodges the head of the astragalus, the support of which it eminently contributes. It is very dense in its structure. There is also a short and very firm

band passing from the anterior part of the os calcis to the outside of the naviculare, completing the cavity externally. This joint is lined by a synovial membrane, which communicates with the anterior articulation between the astragalus and os calcis, as before mentioned. It is spread over the corresponding surfaces and ligaments we have been describing.

From what we have said, it appears that the os calcis is firmly connected with the naviculare, though in contact only by a very narrow spot; the ligaments cross the head of the astragalus in their course, and their apparent use is to support the latter, at a point which appears so deficient, when examining the mechanism in the dry skeleton. The os calcis is more extensively articulated with the cuboides by cartilaginous surfaces slightly concave and convex in opposite senses. The joint is secured by two ligaments, a superior or dorsal, an inferior or plantar. The first is broad and thin, composed of short parallel fibres passing rather obliquely forwards from the upper and external parts of the os calcis, to the superior rough surface of the cuboides. It is often formed into two separate longitudinal bands. It lies under the peroneus tertius. The inferior ligament is the longest, and strongest of all the ligaments of the tarsus. It is attached behind to the middle of the inferior surface of the calcis, passes horizontally forwards, and is fixed principally into the oblique protuberance observed on the lower surface of the cuboides. It is formed of a great number of fibres, divided into several bundles, which diverge rather as they approach the cuboides. The inferior ones, or the most superficial, are much longer than those more deeply seated, and are continued under the tendon of the peroneus longus, part of whose sheath they form, to the posterior extremities of the first and second metatarsal bones. The upper plane is shorter in its course, and fixed behind the groove for the peroneus longus. The ligament is covered below by several muscles of the foot, which have partly their origin from it. It should be remembered that this joint is in the same transverse line with the one between the astragalus and naviculare.

For the articulation between the naviculare and cuneiform bones we have in the first a cartilaginous surface divided into three planes, in the latter corresponding surfaces covered by articular cartilages continued laterally into their mutual articulations. It is secured by three dorsal ligaments, attached to the upper and lateral portions of the circumference of the naviculare, passing one internally to the first cuneiform, another in the middle to the second, and a third more externally to the outer cuneiform bone. They leave intervals filled by cellular tissue: the internal is the largest; and thicker at its inferior edge. The plantar ligaments have been described as three also, but they are too irregular for distinction, appearing as fibrous bundles passing between the opposite bones, confounded at their attachment to the naviculare. This joint is strengthened internally by an elongation of the tendon of the tibialis posticus, which is attached to the base of the first cuneiform bone, and continuous with the more internal of the ligaments we have been describing.

The articulation of the naviculare with the cuboides is formed by the contact of two small plane cartilaginous surfaces, lined by their proper synovial membrane, and secured by numerous short ligamentous fibres passing from bone to bone, occupying the remaining space; they are very close and compact. There is also a plantar ligament rounded in form, passing obliquely from the inferior and external part of the naviculare to the opposite point of the cuboides; and a dorsal transverse band, crossing from one to the other, covered by the extensors.

## EXTREMITIES:

The cuneiform bones are articulated with each other by cartilaginous facets connected by ligaments passing from bone to bone, deeply as well as superficially. The dorsal ligaments are transverse, and form really but a single band, continued over the three, and attached in its course to each. The plantar ligaments are also transverse, but not so marked; the one which goes from the first to the second is the strongest: they are covered by an extension of the tendon of the tibialis posticus, one part of which is fixed to the second cuneiform, another to the second metatarsal bone; these are distinguished from the ligaments by the opposite direction of their fibres. We find also many short ligamentous fibres passing between these bones, as between many others of the tarsus, attached to the parts not occupied by cartilage: they add much to the strength of union.

We have here a synovial membrane common to these joints, and that with the os naviculare above described. It is spread over the anterior surface of the latter, over the connecting ligaments, and dips between the cuneiform bones, lining their articulation throughout.

The articulation of the third cuneiform with the cuboides is by means of plane cartilaginous surfaces, provided with their distinct synovial capsule, and secured by ligaments. Of these the dorsal is oblique, small and thin, uniting the opposite edges of bone; the plantar is considerably thicker, and more directly transverse. Here also are many interosseous ligamentous fibres, fixed to the parts not covered by cartilage, or where the bones are not in immediate contact.

*Motions of the tarsal bones on each other.*—The motions which take place between the tarsal bones are very limited, if we except those between the astragalus, and the os calcis and scaphoides. By this chiefly the foot is turned inwards and outwards; the lateral inflexions of the ankle joint assisting the motion but little. In the movement which carries the point of the foot a little outwards, which depresses its internal and elevates its external edge, the naviculare glides on the head of the astragalus, and the os calcis on its lower articulating surfaces: the latter bones approach each other more closely, the interosseous ligament, and the external lateral one of the ankle joint are relaxed, the internal lateral ligament is stretched, especially those fibres which pass to the calcaneum. In the opposite motion of twisting the foot inwards, and bringing the sole to face the other, the bones move in the contrary direction, the inner border of the foot is raised, and the external becomes inferior; the interosseous, and external lateral ligaments are distended. These motions, which are very sensible, may be accidentally forced beyond their natural limits, and give rise to injuries which are too generally referred to the joint of the ankle. The naviculare and cuboides may be moved up and down on the astragalus and os calcis, and the cuneiform bones have gliding motions on the naviculare, the cuboides, and between themselves, by which the concavity of the foot may be a little increased or diminished. The utility of these numerous articulations in enabling the foot to resist the shocks it must often necessarily suffer, and in giving grace and ease to the motions of the lower extremity in progression needs scarcely be insisted on: their great relative size and the very powerful ligaments subservient to them make displacement of more rare occurrence than we might at first imagine, on considering the efforts they have to sustain.

*The metatarsus* (mittelfuss, Germ.)—is composed of five long bones placed horizontally and nearly parallel to each other, so as to form a gently convex surface above, and a concavity below. It is situated between the tarsus and the toes, and is analogous in many points to the metacarpus.

The individual bones are distinguished numerically, beginning from the inside. The first metatarsal bone, that of the great toe, is by much the largest in volume, though rather shorter than the rest; the second is of the greatest length; the third comes next to it, the two last differ but little; the four latter differ very little in size. They all contract a little in the middle, and swell at each end, particularly towards the tarsus, and are divided into two extremities and a body.

The tarsal, or posterior extremity of the first, is oblong vertically, with a semi-circular articular cavity behind, resting on the first cuneiform bone. The inner edge of the circumference, which is convex, gives attachment about its middle to a part of the tendon of the tibialis anticus; below is a blunt projecting process, to which the tendon of the peroneus longus is fixed; and on the outer concave edge a small smooth spot, which is in contact with the second metatarsal bone.

The tarsal are much larger than the digital extremities of the other four, angular, and in close opposition with each other. That of the second is placed farther back than the first, is triangular, with the base upwards; it is wedged between the cuneiform bones, resting on the second by a concave triangular articular surface behind; on the first by a small spot on the inside, and on the third by one on its outer side. In the last aspect there are two other articular facets in front of the last joined to the third metatarsal bone, surrounded by asperities for ligaments: the edge above, and the point below are also rough, for the same purposes. The tarsal end of the third is triangular in the same direction as the preceding, articulated by a plane surface behind, with the third cuneiform bone. On the inside are two small facets contiguous to corresponding ones in the second metatarsal; on the outside a smooth spot above, articulated with the following bone, and a rough depression beneath for ligaments. It is rough also above and below. In the fourth, the tarsal extremity is more quadrilateral: behind it is articulated with the front of the cuboides; on the inside with the same bone, and with the third; on the outside with the last metatarsal. Below, and in front of these articular spots, the bone is rough for ligamentous attachments. The tarsal end of the fifth or last metatarsal bone is larger than those of the preceding. It presents behind an oblique triangular articular surface for the cuboides; above and below rough and unequal borders, the former giving attachment to the peroneus tertius, and both to ligaments; on the inside a small articular facet in contact with the fourth; and on the outside a rough eminence projecting backwards, to which the peroneus brevis is fixed, and a portion of the abductor of the little toe.

The bodies of the metatarsal bones are concave from before backwards below, and gibbous above, very irregular in form, and scarcely admitting of regular divisions into surfaces. That of the first is of a triangular prismatic form, with the upper surface convex, and inclined a little inwards; the inferior concave, covered by the flexor brevis of the great toe; the external flat and large, corresponding to the muscles which lie between these bones. The bodies of the rest may be regarded in four aspects; the dorsal presents in each a blunt rising line, which divides the attachment of the interossei; the plantar offers a smooth surface for muscular attachments; the internal and external exhibit variously inclined surfaces, of different breadths, continuous with the two former, smooth, and covered by the muscles which arise from them, and fill the interspaces. In the fifth the body is curved a little from within outwards, and its external side, or rather edge, gives origin in part to the

## EXTREMITIES.

the abductor of the little toe; the dorsal surface is inclined considerably outwards, and terminates on the inside by a prominent line; the plantar surface is covered partly by the flexor brevis of the same toe. In all the dorsal surface is covered by the tendons of the long and short extensors, by vessels and nerves, and the plantar by the deep-seated muscles and tendons in the sole of the foot, by ligaments, and by larger blood vessels and nerves.

The digital, or anterior extremity, is very similar in all. It presents a rounded articular surface, called the head, supporting the first phalanx of the toes: this extends further from above below than transversely, in which direction it is compressed. The circumference is rough, offering above a sensible groove for ligaments, and on each side a hollow, in which the lateral ligaments are fixed. The articular surface is prolonged further below than on the dorsal aspect, and terminates on each side by projecting tubercles. In the first this lower surface is divided by a prominent line into two pulleys, on which the sesamoid bones glide, which are placed below this joint of the great toe. In this bone also the articular surface has a much greater proportional breadth.

The metatarsal bones resemble in structure and formation the other long bones, with this exception only, that the smaller ones are sometimes developed from two points of ossification, one for the tarsal extremity, and body, another for the digital: in the first there are always three.

*The articulations of the metatarsus with the tarsus.*—The first bone of the metatarsus is articulated with the anterior surface of the first cuneiform; the second with the three cuneiform bones; the third with the corresponding cuneiform; the fourth and fifth with the cuboides. The opposite articular surfaces are covered by thin cartilage, and their relations preserved by ligaments above and below; they are all lined by synovial membranes common in general to these joints, and to the articulations of the metatarsal bones between themselves.

The dorsal ligaments pass from each metatarsal bone to those bones of the tarsus with which they are articulated. From the first there passes a broad and thin band to the first cuneiform, attached to the superior surface of each. From the second, which is let in between the three cuneiform bones, we find three ligaments crossing, one internally to the first, another in the middle to the second, a third externally to the third cuneiform: the first and last are oblique in their course, the second passes directly from before backwards. The dorsal ligament of the third is short, and goes straight to the third cuneiform; those of the third and fourth are attached to the upper surface of the cuboides; they are more or less oblique, and by no means constant in their forms or situation, the dorsal ligament of the fourth being often attached to the third cuneiform. They are all covered by the extensor tendons.

Of the plantar ligaments, which are analogous in direction and attachment to the dorsal, that passing from the first metatarsal is very strong, and the joint is strengthened also by an extension of the tendon of the tibialis anticus, which is fixed to the inside of the tarsal end of that bone. The plantar ligaments of the second are similar to those above. That which passes from the first cuneiform is thicker, and larger than the other, reaching to the base of the third metatarsal; the other two are covered and strengthened by a portion from the tendon of the tibialis posticus. The inferior ligaments of the others are small, yet distinct, and of various lengths. The plantar ligaments are much strengthened by the numerous tendinous sheaths which are found in the sole of the foot, and particularly by that of the peroneus longus,

which crosses most of them as it passes along to reach the first metatarsal bone. The ligaments, both above and below, are composed of short and close parallel fibres, following longitudinal, oblique, or transverse directions, according to the relations between the points to which they are fixed. They are separated by intervals filled with cellular tissue, and giving passage to vessels. The synovial membrane, lining the joint between the first metatarsal and cuneiform bones, is distinct, and offers nothing remarkable in its distribution. That lining the triple articulation, formed by the second with the three cuneiform bones, is continuous with the synovial membrane, lining the articulation between the two first of these bones. A separate one is found spread over the joint of the third metatarsal and cuneiform, and sending off two small lateral elongations, which dip between the articulations of the third with the second, and fourth metatarsals. It often communicates with the former at the point where they are in contact. Another synovial membrane belongs to the articulation of the two last metatarsals with the cuboides, common also to that between the two former of these bones.

*The articulations between the metatarsal bones,*—are formed behind by the contact of lateral articular facets, with the exception only of the first, which touches the second without being articulated with it. These two bones are united by short ligamentous fibres passing from one to the other, of considerable strength; the others are connected by dorsal, plantar, and interosseous ligaments. The dorsal are transverse, and three in number, passing from one bone to the next, irregular in form, and attachment, appearing in some subjects as a single transverse band. The plantar are similar in number and direction, but in addition we find several small slips passing from the fifth to the three next metatarsals, separated by cellular tissue. The interosseous ligaments between the posterior ends of these bones are formed by numerous short fibres, occupying the parts not covered by cartilage, and tending very materially to secure their relations. The anterior extremities of the metatarsal bones are not in absolute contact, but they are firmly connected together by a transverse ligament passing below them, and attached to each bone, resembling the ligament described as passing between the digital ends of the metacarpal bones in its form and direction.

The metatarsal bones have but an obscure motion on the tarsus, on which they may be slightly elevated and depressed. They may be moved also so as to approach each other in front, and augment the depth of the concavity of the sole; this effect is produced chiefly by the motion of the first and last towards the long axis of the foot, and is in consequence of muscular action: when the foot is flattened by pressure they are forced farther apart mechanically.

The toes, forming the last division of the foot, are five in number, placed horizontally side by side, composed of rows of small bones extending longitudinally one beyond another. We reckon them numerically, beginning from within. The first and last are known also by the names of the great and little toe. The second is rather longer than the first, the other three diminish successively in length. We find three bones, named phalanges, in all, excepting the first, which has only two; these are termed, from their situation, the first or metatarsal phalanx, the second or middle, and the third or ungual; in the great toe the bone of the middle phalanx is deficient. The two bones of this last are very strong, and exceed very much in volume the different rows of the other toes which are slender in form, and comparatively weak. The bones of the first phalanx are the longest; those of the second are very short, as also the third. They

## EXTREMITIES.

all swell considerably at the extremities, and are contracted in the middle part or body. They resemble the fingers very nearly in the material points of their formation, differing from them chiefly in size and mobility.

The first phalanges are by much the longest, and the bones are more rounded than the corresponding ones in the fingers. They are hollowed below, particularly near the extremities, where the flexor tendons lie, the edges giving attachment to the sheaths which confine them. The posterior extremities are concave for the heads of the metatarsal bones, the anterior have condyles, and a middle depression for the second phalanx. The two opposite articulating surfaces between these bones and the corresponding ones of the metatarsus, are crufted by cartilage, and secured by lateral ligaments, as in the fingers. These are thick and strong, passing from the end of one bone to the opposite. The joint is strengthened below by a transverse ligament, covering it from side to side, contributing to the sheath of the flexor tendons; and is further supported by these last, by the extensors, and the smaller muscles which surround them. The synovial membrane is loose and extensive; in the joint of the great toe it lines the two sesamoid bones. These small bones are unequal in size; the internal is the largest, oblong, gibbous below, concave longitudinally above, and a little convex transversely, covered in the last aspect by cartilage, and resting on the head of the metatarsal bone in the two hollows already mentioned, so as to be separated by a small interspace. They are connected by ligaments to the first bone of the great toe, as the patella is to the tibia, and glide backwards and forwards in the different motions of the joint, defending it effectually below, giving an advantageous purchase to the muscles which are fixed to them, and preserving from pressure the tendon of the long flexor, which runs between them. These bones are rarely met with in the other articulations. The motions between these bones and the metatarsus may be effected in every direction, except rotation, and are in general more limited than in the fingers. The toes, however, can be inflected backwards, or extended on the metatarsus to a greater degree than they can be bent. The advantages of this mechanism, so widely different from what we noticed in the hand, may be particularly noticed in standing on the toes, and in progression, and will be examined hereafter.

The second phalanges of the four lesser toes are so short and compressed longitudinally, as to have scarcely the usual characters of the long bones. This is a distinguishing point, in comparing them with the second phalanges of the fingers, which they otherwise resemble in miniature, giving attachments in a similar manner to flexor and extensor tendons, and to the fibrous sheaths of the former. The articulations are also analogous; the motions, which are those only of flexion and extension, are more limited.

The last, or ungual phalanges, five in number, resemble those of the fingers both in structure and formation. That of the great toe is strong and broad; the others are more than proportionably small. This last difference is the principal one between them and the fingers; the articulations and motions are very nearly the same; the latter may be a little more limited. In children they are very moveable: this mobility diminishes as we grow up, and is often completely destroyed in advanced age, owing most probably to the confinement of our shoes. The metatarsal rows have three points of ossification, the others have two, and very frequently only one.

From the assemblage of the bones we have been describing, there results a long, broad, and partly vaulted basis, for the support of the weight above, secured by numerous and

strong ligaments binding the arch beneath. The principal points of bearing are on the lower part of the heel bone; the outside of the foot in nearly its whole length; especially the posterior end of the metatarsal bone of the little toe; the anterior ends of all the metatarsal bones, and most conspicuously that of the great toe, which is proportionably strong. When the heel is elevated from the ground, the whole pressure is on these last mentioned points, and on the toes, which compensate, by their augmented breadth, their comparative want of solidity. The vaulted form gives a space in which the vessels and nerves can pass free from compression; and the number of the articulations, by distributing the shock over numerous slightly yielding surfaces, prevents the injurious effects which might otherwise arise from leaps, or falls on the feet.

*Mechanism of the lower extremities.*—In supporting the trunk, the hip bones are placed between two opposite efforts; viz. the weight of the body transmitted by the sacrum; and the resistance opposed by the limb below in the direction of the cotyloid cavity. The depressing impulse acts in a plane posterior to that of support, tending to make the hip bones move backwards on the thighs, if they were not counterbalanced by muscular efforts. The base of support, as far as regards the ossa innominata, is contained between the plane of the vertebral column behind, and that of the thigh bones in front; a space which varies in different individuals, and which is comparatively narrow in infancy, from the more oblique direction of the hip-bones, which brings the thighs more immediately under the vertebral column. As the ossa innominata become more horizontal, the base of support is rendered wider, and the muscles being at the same time more fully developed, give it additional security. This is one source of the difference in gait in manhood and infancy. Another is found in the disposition of the cotyloid cavities. As they are at a distance from the points of ossification, they are almost wholly cartilaginous for some time after birth, and therefore can offer but a feeble resistance to the thighs, quite insufficient for standing or progression, until the place of cartilage is supplied by bone. Add to this, that the two joints are comparatively nearer to each other; which circumstance, though it give facility, must necessarily diminish firmness. The greater proportional distance in the adult throws the thighs further apart above. In females this distance is greater than in the male, which gives a peculiarity to their walk, a more observable rolling of the hip in the successive advancement of each limb. This is not to be seen in the infant female, where the position and form of the hip bones differ but very little from those of the male of the same age.

The femur, which is the only bone in the thigh, is curved considerably forwards in the middle; hence a larger space is left behind for muscles; and the base of support, afforded by this bone to the trunk, is directed forwards, so that the latter is sustained in the direction, in which it has the greatest tendency to fall. The neck of the bone, besides increasing the extent of rotation, enlarges transversely the base of support; gives the body a greater firmness in standing, without impeding progression, since the head of the bone, and not the body, is the centre of motion. If the thigh bones possessed no neck, but were kept equally far apart, by increasing the distance between the cotyloid cavities, the attitude of standing would be equally secure, the transverse base of support being still the same; but progression would be impeded, as it actually is in the female, from the greater transverse diameter of the pelvis. The head of the femur, sunk into a deep cavity, is forced, in

## EXTREMITIES.

supporting the trunk, against the most resisting part of this cavity, viz. under the anterior spines. The strong ligamentous bands which strengthen the capsule in front and above, are so disposed as to augment the resistance to any effort of the thigh-bone in that direction, and to restrain any part of the head which may not be contained in the acetabulum. The interior ligament also adds to the firmness of the joint; preventing, by its tension, the displacement of the articular surfaces in every effort which forces the head upwards; an effort which, from the pressure of the trunk, is almost constantly operating. In the infant, the body of the bone is nearly straight, a conformation unfavourable to standing, according to the reasons above alleged: the neck is shorter, and consequently the base of support diminished; it is cartilaginous, and therefore less able to endure, for any time, an attitude which demands solidity in the sustaining parts. These are other reasons for the insecurity of the station and progression of young children, and shew by contrast the advantages of the form of the adult bone.

In the knee, we are struck with the extent of the articular surfaces, and the number and strength of the ligaments which connect them, so well adapted to sustain the weight transmitted by the thighs; the crucial ligaments limiting and maintaining the extension of the leg, preventing it from passing in this direction beyond the axis of the thigh; the patella in some measure restraining its flexion, protecting the joint, and more particularly favouring the action of the extensor muscles, which play so important a part in the functions of the lower extremity. The perpendicular direction of the leg is very advantageous in giving firmness; to this end also the immobility of the two bones which compose it seems directed. The tibia, solid and broad at either end, alone receives the pressure and continues it to the foot; the fibula serves principally to afford attachments to muscles. This disposition, so different from that observed in the analogous part of the upper extremity, bears an obvious relation to its different function. In infancy the patella is scarcely perceptible; its absence must be unfavourable to the power of the extensors, and may be one cause of the feebleness observable at that period; and further, its want is felt in kneeling.

The foot is admirably adapted to its office of sustaining every effort continued from above. It is articulated at right angles with the leg, through which it receives the weight of the body in a perpendicular direction, bearing directly on the upper surface of the astragalus, the whole length of the foot resting on the ground. The articulation is situated nearer to the posterior than to the anterior part of the feet, which gives to the base of support a greater extent forwards, a direction towards which the line of gravity naturally inclines. The lateral descent of the malleoli materially secures the firmness of the ankle joint. The breadth of the foot, increasing gradually towards the front, the length of the metatarsal bones, the direction of that which sustains the great toe, its situation and want of mobility, are other circumstances marking the distinction between the hand and foot, and adapted to increase the solidity and extent of base afforded by the latter. The functions of the foot are assisted also by its concave form, which enables it to gain a kind of hold of the bodies on which it rests, and to accommodate itself to unequal surfaces, an advantage almost destroyed by the use of shoes, but eminently conspicuous in those people whose feet are not cramped by artificial means of defence. In its posterior half nearly it rests on the ground by its outer side, composed of the solid bone of the heel, and the os cuboides, the inner side representing an

arch, and placed at a distance from the plane below; in the anterior half the weight is principally supported by the inner side, where we find the solid bones of the great toe very little assisted by the external edge.

Every thing in the structure of man evinces that he is designed by nature for the erect posture: we shall notice here those proofs only which are deducible from the framing of the extremities. One of the most obvious is the great disproportion in the respective lengths of the upper and lower limbs, and the greater comparative strength of the lower. Other marks are found in the width and direction of the hip bones, in that of the neck of the femur, in the articulation of the leg at right angles with the foot, in the size and length of the latter, and the predominance of its solid over its moveable parts. We may remark also the flattened chest, and the shoulders set off by long clavicles, so very different from the construction of these parts in quadrupeds, where the chest is compressed laterally, and the anterior extremities approach each other in front for the better support of the body. The form of the hand, and the modes of articulation between the several bones of the upper extremity, are among the numerous and evident arguments that the erect posture is natural to man, and we believe we may add, peculiar to him. In all the positions, produced by different motions, this posture is more or less preserved; so that, before we enter on progressive movements, it will be well to consider separately the simple act of supporting the body, which they necessarily include.

*Station*—or the act of standing, in man, as far as the lower extremities are concerned, will be the first point for our observation. In this attitude it is necessary that the perpendicular line, which passes through the centre of gravity of the whole body, should fall somewhere in the space intercepted between the two feet, or on the sole of the foot itself, if we are supporting ourselves on one only. This centre of gravity, when the body is erect, has been proved by Borelli to be placed between the hip bones, “inter nates et pubem,” in the human subject. To favour this disposition, we find a vertebral column curved alternately in opposite directions, and placed obliquely with regard to the direction of the ossa innominata, by which means the distribution of the soft parts is more easily managed, the balance preserved, and permanent station much facilitated. If this obliquity did not exist, and the vertebral column had been straight, it would approach too nearly the line of direction of the leg and thigh, a disproportionate quantity of the mass of the body would be placed in front of the line passing through the centre of gravity, which would continually tend to make the body fall forwards in prolonged station or progression. In the orang-outang the angle, which the vertebral column raised perpendicularly makes with the hip bones, is much more obtuse than in man, and the equilibrium is preserved by the length of the arms; the same may be observed of the gibbon, the simia lar of Linnæus. In quadrupeds this angle, under similar circumstances, is still more obtuse, and the efforts they make to remain upright on the hinder feet are continued with difficulty, more especially if not assisted by some other peculiar advantages of construction, as in the bear, for instance, by the length of the heel. In man, the hip bones united to the sacrum form a circular support, by means of which the columns below are not inclined to the trunk, but sustain it in perpendicular lines. If they had converged above, they would have formed an angular support, not so capable of resisting the pressure, and requiring a constant and powerful exertion on the part of the adductor muscles. As it is, the columns are pressed on perpendicularly by the transverse width of the hip bones,

## EXTREMITIES.

so that the pressure may be said to render them more firm and steady. The long bones of the lower extremity in man are placed nearly vertically on each other, and on the foot. And we may just remark, that even in station a succession of columns of the same size is probably more advantageous than a single one, equal in bulk and length to the whole: this has been demonstrated in the case where the weight is upheld by columns supposed to be flexible. The direction of the head and neck of the femur has been already mentioned as increasing the base of support, and we may add that the oblique position of the latter decomposes, in some measure, the pressure of the trunk from above, and renders it less sensible than if it had been vertical; avoiding at the same time the disadvantages arising from an inclined position of the whole column, as mentioned above. By the arch of the necks also the thigh bones are projected from under the hips, and sustain the trunk with greater constancy and freedom than if they had been placed vertically beneath it during its different inclinations. The thighs, charged with the whole weight above, transmit it to the leg at the knee joint; somewhat differently, however, in the adult, and in the aged. In the latter the spine is bent forwards, and to preserve the balance the thighs are necessarily also bent, and press obliquely on the leg, a disadvantageous bearing, as requiring greater muscular efforts, and soon becoming on this account wearisome. It is through the tibia alone that the pressure is communicated to the foot, which finally supports the whole weight. The arch of the latter is favourable to station only inasmuch as it favours the adaptation of the sole to inequalities of surface. In progression it may give ease and grace, but the long and somewhat flattened foot is probably best suited to firmness of station. The concavity is lessened by the pressure, which acts most sensibly on the anterior and more moveable part: it is very evident, when the foot comes with force to the ground, and it may be proved also by the aching and uneasiness produced by wearing short shoes, which impede the elongation of the foot. A question has arisen concerning the most advantageous base of support, or what opening between the two feet is best suited to security of station. An answer equally applicable to every case cannot readily be found; the nearer it approaches a square, including the feet, the better. Still different individuals must require different bases as suited to their own form. In every case, if the separation be too wide, the limbs lose their perpendicular bearing, and become inclined to the trunk. The smaller the angle made by two lines produced backwards in the direction of the feet, the better: it seems, indeed, that a parallel direction of the two feet is the most natural, as we see it in children and in the greatest number of adults, especially of those who have not been instructed by art. The body has a tendency to fall forwards, which is partly counteracted by the length of the foot; increasing the base of support in the anterior direction. Now if the foot be turned much outwards, the base is necessarily shortened towards the front; and, as in station, the trunk has no disposition to fall laterally, what the base gains in that direction is in no degree equivalent to what is taken away from the other. The same observation applies to turning the toes inwards; but as this never takes place to any considerable degree, an abuse of it is less to be apprehended. The unnatural position, in which education teaches us to place our feet, with the heels forming an obtuse angle behind, is contrary to the whole mechanism of the limbs, is uneasy, and insecure. In different gymnastic exercises the feet are placed so as to offer the greatest possible resistance to the probable direction of the effort they will have to withstand. In wrestling, where the force in

the first instance is generally applied laterally, we observe the feet parallel, and at a considerable distance from each other. Constant attention, however, is absolutely necessary to change this base, if any unexpected impulse be made in a contrary line. A deficiency in this respect is the reason why inexperienced wrestlers are so readily pulled down forwards, or thrown on their backs, their exertions being uniformly directed to oppose the expected ones of their adversaries; if these be suddenly altered, there is no adequate power of resistance. In boxing, the base is increased from before backwards, the feet are placed nearly at right angles and far apart, the knees are bent a little, and the trunk lowered. Here the impulse is expected in front, and the attention is particularly directed to oppose it in that point. This, in short, is one of the great principles observed not only in these exercises, but in every laborious exertion, as in pushing or pulling, where the line of opposition does not vary. Whatever be the direction or distance of the feet from each other, no muscular effort can prevent the fall of the body, whenever the perpendicular line from the centre of gravity falls without the quadrilateral space intercepted between the feet. And a man can support a weight much heavier than himself, provided that the line from the centre of gravity of such body fall within the base of support.

Our observations hitherto are principally applicable to station, with the trunk erect. Let us now suppose the feet fixed securely on the ground, and the trunk moving in different directions by means of the articulations of the hip with the thigh-bones. In bending forwards, if the motion be prolonged considerably, the centre of gravity is no longer supported, and a fall is the immediate and necessary consequence. We have before remarked, that the articulation of the sacrum with the ossa innominata is in a plane posterior to that of the feet. Now, if in bending forwards, the hip-bones move on the thighs, so as to bring the two bases into the same plane, the centre of gravity is easily thrown forwards beyond them, and a fall is the result. To counteract this, when the trunk is bent much forwards, we at the same time carry the upper part of the lower extremities backwards, the feet remain advanced, the leg and thigh are inclined backwards, so as to form an angle with the body. In extending the body on the thighs, and carrying it back beyond the perpendicular, as there is no extended base of support behind, analogous to that formed by the feet in front, we are obliged to bend the knees, in order to bring the centre of gravity within the space occupied by the feet. If the lower extremities are maintained in an upright position, while the trunk passes behind the perpendicular line, a fall is inevitable. Lateral inclinations of the trunk on the thighs are necessarily confined; since, in order to lower it on one side, the opposite limb must be proportionably raised; when both feet touch the ground, it is almost completely prevented, so that the lateral balance is seldom lost, especially as we can at pleasure widen the base of support.

The power of standing on the toes results from the mode of their articulation with the metatarsus, which allows of extension or inflection upwards, beyond the axis of the latter. By this mechanism we rest on the whole length of the toes, not merely on their points, which would be utterly incapable of supporting the weight; here too the sesamoid bones are essentially useful, the pressure bearing directly on them, as it does on the patella in kneeling. In this attitude the feet are extended on the leg, and form an obtuse angle with the toes, which constitute the basis of support; the legs and thighs are in the same straight line, and the trunk is projected a little forwards by the elevation, so that the centre of

## EXTREMITIES.

gravity is brought over the contracted plane, which now forms the base of support, lessened very much in length posteriorly by the loss of the tarsus and metatarsus. The same difficulties occur if we stand on any pointed, or narrow body, and for the same reason, *viz.* the diminution of the space in which the vertical line from the centre of gravity must fall, in order to preserve the equilibrium. This applies also, and more forcibly, to the cases in which we stand on the toes, or heel of one foot only. In the last instance the foot is bent, the sole elevated, the rounded heel alone touches the ground by a very limited surface, great muscular exertion is required to keep the line of gravity vertical, the body vibrates on every side, and the attitude is necessarily soon lost or discontinued. We have not so much difficulty in standing on the heels of both feet, though this is far less easy than on the toes, on account of the points on which the weight rests. Standing on a single foot, with the whole sole on the ground, is an attitude more easily maintained, on account of the greater length of contact, and the less muscular exertion necessary to insert or erect the trunk so as to bring the line of gravity within it. In this position the body is more or less inclined on the limb which supports it, and may be moved with facility in every direction by means of the joint at the hip. The long neck of the thigh-bone is here eminently useful, by widening the base of support afforded above to the trunk; and the position cannot for an instant be maintained by animals, who, besides other obstacles, have a very short neck to the femur. It is obvious that station on one foot must be more difficult than on two, as in the last case it is not only the feet, but the plane intercepted by them, which form the base, and much less exertion is required to keep the line from the centre of gravity within it. We must have observed also, that when in station on one foot, the trunk is much inclined in any direction, we throw out the other limb in the opposite one, in order to keep the centre of gravity vertical to the base: and if we stand on the toes or heel of one foot, not only the other leg, but the arms also, are called into action to preserve the equilibrium, which is perpetually lost and regained by the tottering trunk, and shuffling base. A fixed stability is utterly prevented by the difficulty of keeping the balance even under the greatest muscular exertions.

In sitting, the support is afforded by the tuberosities of the ischia, the thighs and the interval between them, and by the legs also, if we sit on the ground with them extended. This is a firm position, easily continued, especially if the body is inclined a little forwards over the base; if it is inclined backwards a fall may easily take place. On this account we have generally backs to our seats, to allow the trunk to recline, when the muscles are fatigued by supporting it in its position of inclination forwards. The legs and thighs are concerned only in a secondary way in this posture, as the principal support is afforded by the tuberosities of the ischia resting immediately on the surface below.

Kneeling is another attitude in which the lower extremities are employed, but the base of support is extended posteriorly, consisting of the space included by the legs, which are projected backwards under the trunk. Hence the body, if erect, is disposed to fall forwards; we require a resting place in front, as we throw the hips backwards, to bring the line of gravity over the legs. This posture is far from an easy one, since it requires a constant and unfavourable exertion of muscular force. The use of the patella has been already explained.

The importance of the general law, by which it is necessary that a vertical line passing through the centre of gra-

vity should fall on some point within the base of support, is strikingly exemplified by the following observations. If we stand with our back and feet touching a wall, and then make a profound bow forwards, we inevitably fall, as the vertical line from the centre of gravity soon over-reaches the base of support. Again, when sitting with the trunk and legs perpendicular to an horizontal plane, we cannot rise from our seat; because the centre of gravity of the trunk falls far behind the feet: we are obliged consequently either to incline the trunk very much forwards, or draw the feet backwards under it, in the first case changing the centre of gravity, in the latter the base of support; and then by muscular efforts the thighs are easily extended on the legs, the trunk suspended, and the whole body erected; operations extremely difficult, if not impossible, supposing the original position had been preserved. Our notions of station would be very imperfect if we did not take muscular exertions into the account; it is in vain that we place a dead body so as to bring the centre of gravity over the base of support; the bony columns are no longer regulated by the varied efforts of numerous muscles, as in the living subject; the machine is incomplete, and instantly gives way to the pressure. The same phenomena occur if fainting comes on in the erect posture; the head and neck incline forwards, as also the trunk; the bones bend on the thighs, the latter on the legs, and these again on the feet. We must not therefore confine our attention to the idea of bony columns pressing vertically on each other, but recollect that they have highly moveable articulations, which require some strong external efforts to give them positive stability. These exertions are more or less powerful as the bones depart more or less from a vertical bearing on each other. Hence the anterior extremities of quadrupeds possess fewer and less powerful muscles than the posterior: as, in the first instance, the bones are directly extended on each other, and press vertically on the ground; in the last, they form angles more or less open, which can be preserved only by a constant exertion of muscular force. The elephant is an illustrative exception to this observation; his hind limbs are nearly vertical columns; a mechanism which diminishes the quantity of muscle otherwise necessary to support his enormous bulk. In insects, on the other hand, the joints are bent at very acute angles; a structure less inconvenient than we might at first suppose, as on account of the smallness of their body, the weight is diminished in a sub-duplicate ratio to their size. In birds who sleep perched on trees there is a peculiar construction, by which the mere cessation of muscular action, the allowing the body to sink, and the knees to bend, induces a mechanical contraction of the toes, which grasp firmly the body on which they rest, and secure their position when at rest. In the grallæ tribe, in the stork for instance, who stands motionless for hours waiting for his prey, there is a particular construction in the articulation of the knee, which enables him to stand without much muscular exertion.

*Progression*—may be effected in many different ways, of which we shall examine only the most ordinary and simple. In walking, the action, which carries the body forwards, backwards, or to either side, consists in alternate motions of the lower extremities, in which each of them becomes, in its turn, the fixed point on which the whole weight of the body is supported; the limb which moves, giving in its elevation an impulse to the trunk by means of the hip bone. Each of these motions is called a step, and a sustained succession of them constitutes progression: and in order to understand the latter, we shall examine the mechanism of the step under different conditions. In walking, if we suppose both

## EXTREMITIES:

Both feet to be on the same transverse line, the limb (say the left) which makes the first step, is raised from the ground and advanced, by bending the hip joint; it is then extended, and lastly, the foot preserving its advanced position, is fixed on a different spot; so that the centre of gravity of the body which, during the advance of the left leg, was sustained by the right, is moved forwards by a simultaneous movement of the trunk; and the line of gravity falls between the two feet. If the step is short, the hip and trunk move but little; if it be long, and the left leg carried far beyond the right, there is an evident rotation of the right hip, and consequently of the trunk on the corresponding thigh. By this horizontal rotation, which carries the left side of the body obliquely onwards, the extent of the step is greater than it would have been by the simple bending the thigh; and we see it in fact most evidently in long strides, where the rotation is so great, as to bring the shoulder of the advanced side immediately in front, the hip moving through the quarter of a circle, giving thereby an additional impulse to the limb below. As the step is shorter, this lateral rotation is less observable, till in some cases it can be no longer noticed. It is more evident in the female, from the greater transverse diameter of the pelvis; and is particularly striking in individuals who have a stiff, or ankylosed hip joint, where the limb cannot be advanced by bending the thigh. The short step is effected, on the contrary, chiefly by the alternate flexions and extensions of the joints of one extremity, uninfluenced by any movement of the trunk on the other.

If the feet are not in the same transverse line at the commencement, the limb, which is behind, and inclined to the trunk, is the one to be moved forwards. Here the foot rises, each part quitting the ground successively, from the heel to the toes, by a kind of circular motion. The limb is thus elevated and advanced, and the centre of gravity is carried in the same direction, which latter is effected with greater facility, as the body at the same time leans a little forwards. When this impulse is carried to its full extent, the toes are detached from the ground by the thigh being suddenly bent on the hip, which has been moved forwards, and the limb is carried on as in the former case, the other remaining fixed as the temporary support. The hip and knee joints are then extended, and the foot bent on the leg. The foot touches the ground first by the heel: this is succeeded by a circular motion of the anterior part of the foot round this fixed point, and a corresponding motion of the leg in the same direction, which brings it to a vertical line at the time that the toes begin to bear on the plane below. In these circular motions the foot is sensibly elongated, and its concavity lessened by the pressure, its vaulted form, and the number and mode of its articulations imparting a degree of ease and grace to the whole motion which we look for in vain, where the foot is flat and stiff, and the whole sole quits, or reaches the ground at the same instant. There is, in this case, an awkwardness of gait, and a real inability of walking with promptitude and vigour. This step we have been describing takes place successively in each limb in progression; and differs from the preceding in being more extensive, and depending more importantly on the foot. The impulse which its elevation communicates to the trunk will be influenced however materially by the knee: if this is bent in proportion as the foot rises, the limb loses in one action what it gains by another; the impulse will be stronger as the knee is kept more extended. And when the foot is detached at once, without this rotation, no impulse will be given to the hip by the limb in motion: if the pelvis roll on the thigh which is fixed, it must be by an independent

muscular action, as in the former case. In every case, as soon as the foot has left the ground, the trunk supports the limbs; and carries it forwards. The mechanism of the step backwards will be easily understood from what has been said: we observe only that the foot is raised more immediately by bending the knee; and that when the step is prolonged, there is an evident horizontal rotation of the trunk in the same direction. The side step is produced by gently bending the knee to detach the foot from the ground, and then abducting the thigh; or by lifting the whole limb by a lateral inclination of the trunk on the opposite one, and then separating them, the knee being all the while extended.

Walking is a succession of these motions, and requires for its regularity an equal length of both limbs; a shortness of either limb induces a sinking and relative inclination of the whole trunk to the corresponding side, every time that the deficient extremity touches the ground. In the most natural mode of walking, one foot does not quit the ground entirely, until the other touches it wholly, or in a great part of its length: the latter begins to fix itself while the former still rests on its point; the vertical line from the centre of gravity, which fell on one foot during the transportation of the other, being carried forward, and dropping at this time between the two. When the advanced foot is firmly fixed, we throw on it the centre of gravity; the same motion necessarily projects the whole body forwards, and a succession of similar phenomena takes place. At each step the impulse given to the trunk by the limb which has just quitted the ground produces an undulatory motion up and down, and at the same time an horizontal rotation alternating from one side to the other. It is the latter which, from not being sustained equally, produces the deviation from the straight line in walking forwards; so constantly observed if we walk blind folded, where consequently we cannot correct incidental errors by the sight. The best chance of walking straight in this case is by taking very short steps, and for the reasons insisted on above. In fact, the centre of gravity is not, when we carefully endeavour to attain it, moved forward in the same straight line, but varies more or less between the lines described by the feet at every step, in a degree proportionate to the extent of each. This is scarcely noticed, but is evident from this simple experiment. If we stand at any distance from a small perpendicular rod, and fix our eyes on any point some way behind it, and in the same straight line, we shall, as we advance to the rod, find this point alternately to the right and left of it, as we move each limb. A proof that the trunk is not carried as in a straight line, but describes a tortuous one, winding from one side to the other. Another consequence of this rolling of the trunk on the opposite limbs in succession, is a swinging motion communicated to the upper extremities: these move, most commonly, in an opposite way to the feet; that is, the right arm moves on at the same instant that the left leg propels the trunk. The use of this cross motion of the arms is supposed to be that of correcting the lateral impulse given to the trunk by the leg in its elevation. In every case of progression there must be a regulated degree of flexions and extensions, which is in some instances provided for by the mechanism of the bones, and their ligaments, but in all depends principally on an uniform succession of sustained muscular actions. The greater difficulty and fatigue experienced in walking up an ascending plane depends upon the greater degree of flexion necessary to raise the limb from the ground; this must be increased as the plane becomes more vertical; the heel is at the same time lower than the toes, and must pass through

more

## EXTREMITIES.

more space in each elevation than in the ordinary case of walking on plain ground. Walking down hill is for the same reasons less difficult; there is less occasion for extensive muscular action. The object is to regulate the impulse which the trunk easily acquires, and to keep the centre of gravity over the feet, by throwing the trunk a little backwards, instead of leaning forwards, as in the preceding case. In ascending also we have each time to elevate the weight of the body by muscular powers; in descending we have only to prevent it from sinking too fast. Mounting steps, or a ladder, or descending either, are still more difficult, as the reasons above given apply more strongly.

Running differs from walking chiefly in the rapidity and force with which the motions of the lower extremities are executed. The mechanism by which they are produced is nearly similar; the remarkable differences are, that the toes only touch the ground, and the whole trunk is inclined very considerably forwards. In consequence of the first circumstance, a small surface only is in contact with the ground; and this can be more rapidly applied and detached, while the extension of the foot upon the leg adds to the length of the limb. From this small extent of the base of support arise the frequent falls in running from trifling obstacles, or slight lateral impulses; and hence, in this mode of progression, we should constantly endeavour to preserve the balance, by preventing the centre of gravity from being removed too quickly from the leg behind, or from being thrown too soon on the one in advance. Running is also insecure from the short time allowed for fixing the point of support; and hence positive stability is lessened inversely as the necessity for it is increased by the quick transition of the centre of gravity from point to point. At each step the trunk is suddenly and violently carried forwards by the limb which has just left the ground, and which must be immediately and considerably advanced to support the centre of gravity. In running very fast, especially on a declivity, so powerful an impulse is communicated to the trunk, that it is almost impossible to stop suddenly; we gradually slacken our pace, still projecting the limbs to support the trunk till the impulse is weakened. In running up an acclivity we always bend forwards, to assist the propulsion of the centre of gravity, which is effected under many disadvantages; we generally do so in running on plain ground, though, when we run carefully, the head and shoulders are thrown back to counterbalance the impulse below. When from fear, or inability to continue the muscular exertions necessary to maintain this posture, the trunk is neither thrown back, nor even kept vertical to the horizon, the runner appears to yield entirely to the impulse, to commit himself almost to chance; his only endeavours being to throw his legs out rapidly and to the greatest extent, to sustain the increasing velocity with which the centre of gravity is carried onward: the ground covered at each step is really immense, the power of balancing is totally lost, and the slightest inequality of surface is sufficient to overturn him with the roughest violence. If he is steady enough to reach the bottom in safety, he continues his course a very considerable way before the impulse is destroyed, and the power of regulating his movements recovered. In running, the lateral rotation of the hip and trunk on the thigh is extensive, from the length of the steps; and the same cause produces an equally great and rapid motion of the opposite arm to preserve the equilibrium, which is more easily lost than in walking.

In leaping, the body may be raised vertically, or with any degree of obliquity. The joints of the lower extremities are first closely bent, and then suddenly extended, so as to propel the trunk; for the ground effectually resists the

impulse, which must be entirely spent on the moveable parts above. The alternate angles, formed by the ankles, knees, and hips, depress the centre of gravity, without altering its bearing on the feet; and the same mechanism enables us to elevate the trunk nearly in a vertical line, the circular motions in opposite directions executed with almost instantaneous velocity, acting in a straight line intermediate to them all. If the flexions were all made in the same direction, subsequent extension would be more laborious, and a perpendicular impulse, such as produces the vertical leap, would be impossible. The mechanism of leaping may be illustrated by comparing it with other motions. The muscular powers being the same, the leap will be more considerable as the levers are longer, and more inclined on each other. Hence animals, whose hind limbs appear disproportionately long, can make the most extensive bounds; we need scarcely instance the kangaroo, hare, squirrel, or grasshopper.

The elevation of the body in a vertical leap is continued so long as the communicated impulse exceeds the power of gravitation; as the former diminishes, the latter again begins to operate, and the body descends in the same line with that in which it had been elevated. It is incapable, while in the air, of altering the general direction derived from the first impulse; although many motions of the extremities may be produced, as we observe in dancing. The ground, from its want of elasticity, communicates no impulse to the body at the moment of elevation. A certain resistance to the action of the muscles on the moveable levers is required. If the ground be soft or sandy, it yields too readily to the impulse of the feet, and leaping is impeded: on the contrary, if the point from which the jumper springs be elastic, as in the case of a flexible board, or a tight rope, there is an evident re-action, considerably increasing the impulse communicated by the exertion of the lower limbs. In jumping forwards the trunk is inclined, and projected in the same direction by the extension of the thigh on the leg. This latter motion is counterpoised or varied, according to circumstances; but it is so essential in every case, that we cannot leap if the knees are kept extended, no muscular action or exertion could then raise the body from the ground. The chief effort is to turn the thigh and trunk balanced on it forwards on the tibia; and the impulse thus given predominates over the others; in leaping backwards, the tibia is the more moveable division of the lever by a variation in the combined action of the muscles employed, determinable by the will. In the vertical leap the body moves up and down in the same line: but if the impulse is given in a line inclined to the horizon at oblique angles, the line described by the centre of gravity will be a parabolic curve, compounded of the uniform straight motion of projection, and the force of gravity, as in other projectiles. While the first predominates over the last, the body ascends; when they are in equal power, the elevation is the greatest; from this point, it descends, the force of gravity acting with increasing effect as the impulse is weakened. The impulse, in this case, may be considerably increased by a previous motion given to the body by running: the impetus is somewhat altered in direction by the violent extension of the extremities, but it acts with almost undiminished force in projecting the body: there are here two causes acting in opposition to gravitation. This kind of leap is facilitated by inclining the body forwards; and, in order to afford a point of support to the centre of gravity, we always find, before the body is elevated from the ground, that one of the legs, generally the right, is much before the other; this position is preserved throughout, for the same reason, or the two legs are brought into parallel obliquely inclined lines, before we reach the ground

## EXTREMITIES.

ground at the end of the leap. If we jump with the feet together, we cannot incline the body much forwards, without losing the balance. In this case, to assist the impulse, we swing the arms backwards and forwards before we make the spring, endeavouring to give some degree of horizontal impetus to the trunk, which must however always be inferior to that obtained by even a short run. The body comes in contact with the ground, at the end of the leap, impressed by a double force, *viz.*; the projectile impetus, and that acquired by gravitation in the descent. We extend the feet on the legs, so as to touch the ground first by the toes; we then yield somewhat to the force, and allow the joints to be bent gradually, so as to weaken and finally destroy the shock. In order to destroy the impulse given to the centre of gravity, we throw back the head and shoulders, and slacken our pace by degrees, till the power of balancing is restored.

The action of dancing, which consists in a rapid change, in various manners and directions, of the lower extremities, principally resembles, in some respects, the *run*, in many others the *leap*. We omit the detail of those extraordinary and amazing feats of agility, which astonish us in the stage dancer, or the tumbler; as they depend, not on any peculiarity of mechanism, but on the powerful, long sustained, or rapid actions of muscles, educated to the task, and preserved by constant exercise in the highest possible state of energy. Hopping is a succession of leaps on one leg only; the actions are otherwise analogous. Skating is a simple motion; the mechanism of which may be readily conceived after the observations we have made: the centre of gravity is brought alternately over the opposite feet, as each glides on the plane beneath, and the balance is preserved by muscular action. Swimming is a more compound action of both upper and lower extremities, involving in its discussion many interesting questions, independent of their functions, and which consequently cannot properly be considered here.

For more detailed information on the subject of animal mechanics, we refer the reader to Borelli, de Motu Animalium; Haller, Element. Physiol. tom. iv.; Barthéz, Nouvelle Mécanique de l'Homme: see Jour. des Scavans 1782-1783. Bichat, Anatomie Descriptive, tom. i. Cuvier, Leçons d'Anatomie comparée; tom. i. sur la fin. There is a catalogue of authors on this subject in Dr. Young's Natural Philosophy v. ii. p. 164.

*Comparison of the upper and lower extremities.*—A review of the differences in the construction of the upper and lower limbs will illustrate the mechanism of their component parts. There is a general resemblance of form throughout; and the essential varieties may be all referred to the principle of mobility in the upper, and to that of firmness in the lower. In man, the extremities are nearly parallel to the long diameter of the trunk; and consequently they must be parallel to each other; but they are not in the same vertical plane. A line drawn from the glenoid cavity of the scapula to the acetabulum, will be very oblique from above downwards and forwards, because the plane in which the former lies is posterior to that in which the latter is found. Hence the arm drops necessarily behind the thigh. The advantage of such a disposition in the upper extremities is, that the principal motions, which are those in the anterior direction, have a greater range than if the glenoid cavity had been seated nearer to the front of the trunk. The extremities differ also in the space, by which they are separated from each other. If we judged only by the intervals between the right and left glenoid and cotyloid cavities respectively, we should suppose the difference to be great;

the long clavicles keeping the first at a greater distance than the pubal portions of the hip bones do the second. This, however, is compensated by the length and obliquity of the necks of the thigh bones, which throw the axes of these bones far without the cotyloid cavities. We have here supposed the legs to be extended, and the arms lying in their natural direction by the sides of the trunk; if the knee and elbow be bent in this position, we shall find the angles are open in nearly opposite directions, that of the knee backwards, and the elbow forwards. These are the only joints in which the articulations are directly inverse in their modes of action; in quadrupeds, this condition prevails from the shoulder and hip to the feet in a very striking manner. The lower extremities are nearer together below than above; while the upper are kept asunder by the intervening body. The lower extremities are rather longer than the upper, in consequence of the great length of the thigh and leg, when compared with the arm and fore arm. For the latter, by the long axis of the hand being in the same line with their length, gain much more than the lower extremity does by the mere thickness of the foot. When the arm hangs easily extended by the side, the points of the fingers reach to about the middle of the thigh; yet there are many varieties in this respect. The solid form, and the broad articular surfaces of the lower, are strikingly contrasted with the slender make and narrow articulations of the upper; the first bearing a marked relation to their principal function of sustaining the body, the latter to their distinguishing character of mobility. At the time of birth the upper extremities are more advanced in formation than the lower. This feature is, however, more remarkable, the nearer we mount to the first development of the embryo; it is gradually lost after birth, and the structure of both is completed nearly about the same period. The different nature of their functions, those of the upper commencing almost immediately, and those of the lower not until a considerable interval after the birth of the child, explains easily the reason of this disposition.

The bones of the hip and shoulder differ more in their form and connections than any other parts of the extremities. The scapulæ are sustained by muscles, allowing a great variety of motion, and are kept apart by the two moveable clavicles in front; the hip bones are bound firmly to the spine, and the articular cavities separated from each other by an immoveable medium. The space between the cotyloid cavities is proportionably greater in the female than in the male. The same excess may be observed in the shoulders, where it arises from the greater comparative length of the clavicle. The breadth of the scapulæ increases in the male the transverse diameter of the shoulders, which on this account is particularly striking from behind; in front they are not proportionably so wide as in the female. It is therefore the proportional excess of width in the hips, and not any decrease in the breadth of the shoulders, which gives to the female figure one of its most prominent features; this distinguishes it from the male, in whom the strong, though narrow, hips are opposed to the comparatively spreading shoulders. These circumstances are sufficiently evident in examining the disposition of the bones; but they become still more striking, by the addition of the soft parts, in the complete subject, where the strongly marked and muscular form of the shoulders, and the contracted outline of the hips in the male, is finely contrasted with the delicacy of the first, and the swelling roundness of the last in the female. The hip bone exceeds the scapula and clavicle in volume, as well as in the firmness of its articulation; it further gives a fixed point of motion to the thigh, by a  
deep

deep articular cavity, whereas the scapula offers a shallow and easily moveable one, yielding to a slight impulse.

The femur exceeds the humerus very much in size, and length, (this last being nearly in the ratio of 46 to 33,) and in the extent of its articular surfaces. Although their motions are for the most part analogous, some differences may be pointed out. The movements of circumduction and rotation exist in an inverse ratio to each other. In the thigh bone, the length of the neck, which is the lever of rotation, gives great extent to this motion, and thus supplies the want in the leg of the motions corresponding to the pronation and supination of the fore-arm, so that all rolling of the foot out and in, when the limb is extended, arises from a motion of the whole limb. The short neck of the humerus, on the contrary, by bringing the axis of the bone nearer the centre of motion, limits rotation; which is less essential, inasmuch as the hand is moved by the pronation and supination of the fore-arm. Circumduction is more confined in the thigh by this very length of the neck, which makes an angular lever of this bone, differing much from the nearly rectilinear one of the humerus. In the first case the axis of motion is not in the long axis of the bone; in the last, it is nearly so; and the difficulty of this motion is proportional to the difference between the two axes, while its facility is greater as they approach each other more nearly. The advantages of this disposition, in giving mobility to the upper, and firmness to the lower extremities, may be readily perceived.

The leg exceeds the fore-arm in the size and length of the bones, the proportions being as 39 to 26. In the orang-outang the ratio of the thigh to the arm is as 9 to 10, and that of the fore-arm to the leg as 9 to 11; which proportions are very different from those of the human subject. The excess of length in the lower extremity of man is seen most evidently when he attempts to move on all fours, as we express it. To correct this disproportion he is obliged to bend the joints of the lower extremities, or to throw them out very obliquely behind the trunk, whilst the upper are perpendicular to it. The leg and fore-arm resemble each other less than the thigh and arm; in the fore-arm the parts are arranged favourably to mobility; in the leg the object is to procure a firm and solid support, which can transport the centre of gravity with ease and safety from one point to another. Of the two bones of the fore-arm, which are nearly equal in every respect, one rolls easily over the other, and the hand is articulated with the moveable bone. In the lower extremity these rolling motions would have been dangerous; to give it firmness, the foot is articulated with the tibia, which corresponds to the ulna, and not with the fibula; the latter possesses no perceptible power of motion.

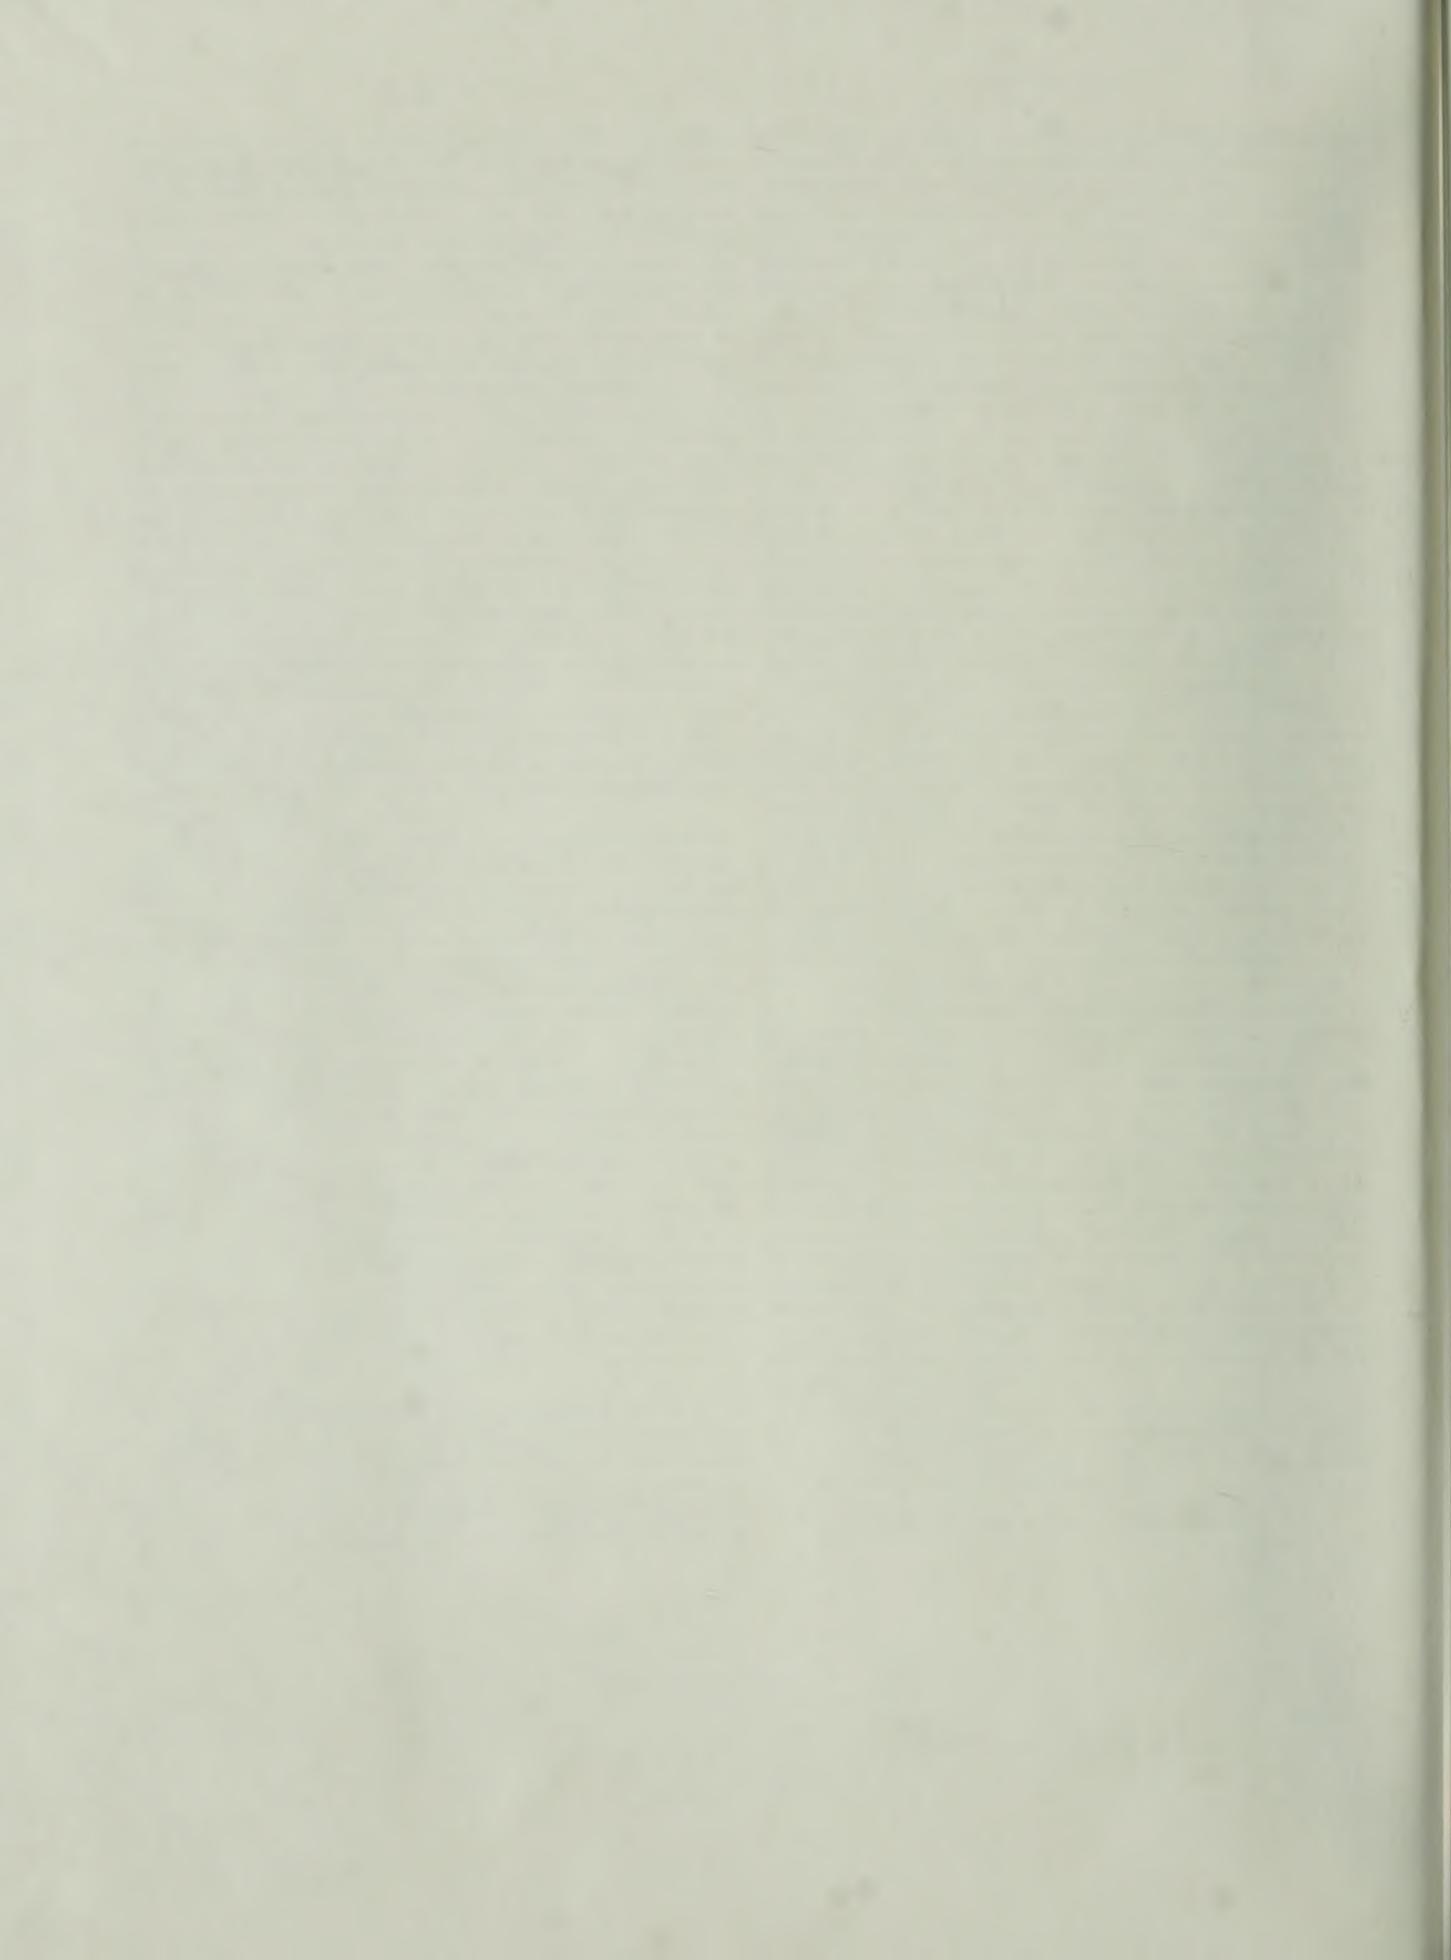

The hand and foot resemble each other most closely in the structure and number of the phalanges, and of the bones which support them; the principal differences occur in the carpus and tarsus, which are the most solid portions. That part of the hand in which its strength resides is less developed, and has far less volume than the analogous parts

of the foot, on which the whole weight of the body in station finally rests. The moveable phalanges, which are the principal agents in executing the functions of the hand, are much longer, and larger than those of the toes, which are not so essential to station or progression. The foot and hand are disposed inversely as to form; the posterior part of the former, and the anterior part of the latter, is the most important, the longest, and possesses the most striking characters. The functions of the hand render it necessary that its plane should be nearly continuous with that of the fore-arm; otherwise the radius could not guide it so precisely over the objects in view. In the foot, the articulation is so disposed that its posterior part offers a powerful lever for muscular agents, and a solid support for the mass above; it is formed by a single bone of the foot, which necessarily adds to its solidity. The metacarpus and metatarsus have a much greater similarity to each other; the latter is the more solid, and offers this principal difference. The metatarsal bone of the great toe, by far the strongest of the whole, has scarcely any motion on the tarsus, and is on the same plane with the others; while that which supports the thumb has a very considerable extent of motion, and is anterior to the rest. This arises from the obliquity in the articulating facet of the trapezium, which is directly transverse in the first cuneiform bone of the tarsus. Further, this bone in the foot is not separated from the other metatarsal bones, by an interosseous space larger than that between all the rest, as is the case with the metacarpal bone of the thumb. These remarkable differences depend wholly on the solidity necessary for station, and the great mobility required for the important offices executed by the thumb in the human subject. In the ape tribe, the great toe on the contrary may be properly regarded as another thumb in its structure and uses. The toes can be inflected further on the back of the foot than the fingers can be on the hand, a disposition which is accommodated to progression, especially to running swiftly; an analogous effect is produced in the hand by the inflection of the carpus backwards on the fore-arm. At the time of birth the important parts of the hand are already well developed; the metacarpus, and more especially the fingers, are sufficiently formed for the infant to seize objects within its reach, and to distinguish some of their qualities. This early development of the organs of touch would seem to bear a marked relation to the corresponding advancement in the formation of two other organs of sense, the eye and ear, they being all associated closely in confirming, or correcting external sensations. The important part of the foot, the tarsus, is far behind in formation, as it is not called into use till some time after birth, till the organs of sense have long been exercised in common, and can now mutually assist each other.

Respecting this comparison between the upper and lower limbs, see Vicq D'azyr sur la comparaison des extrémités entr'elles dans l'homme, et dans les quadrupèdes, in the Histoire de l'Acad. des Sciences 1774.
